>tnx

Hi Hank,

That is an interesting question. So right off the top I will admit I
know of no such beast. However, the formula looks particularly
liberal. Normalized it appears to suggest for a common dipole that
distance would be 1 wavelength, but I would think it from the
literature that this distance would be closer to 5. It is all a
matter of degree in how thin you want to cut it.

At:
http://home.comcast.net/~kb7qhc/antennas/Fields/index.htm
I have done a suite of 6 antennas and have illustrations of the near
field in terms of its Z expressed as SWR to free space. If nothing
else this will give you a picture (for what it's worth). In returning
to the delineation between near and far, my illustrations show only
the first quarterwave out and things have pretty well settle out in
this scale.

> It can also reflect (some or all of) what it does not absorb, ...
> is determined by the ratio of its Z to the line/load
> at the antenna terminal. (Of the transmitter, I believe you mean)

Fine point: I think it must reflect ALL it does not absorb.
Important point: However, I believe the case is that it absorbs little of this energy.

> In this case (bear with me), the source Z is
> NOW found at the load's mismatch, transformed through the line. This
> means matching works both ways (often the singlemost ignored aspect of
> obvious reciprocity in any of these arguments). Such circuit analysis
> is called superposition.

Yes, no argument. Matching does, er um, CAN work both ways on the line, is true. And the TX is, indeed, a "load" for the reflected energy (or wave if you prefer).
I say CAN because the match does work both ways, but that is not to imply that the impedances which exist on the line are matched - nor that one way IS matched while the other is NOT. If there is a mis-match in one direction, there will be another mismatch going the other way. This may be a difficult to understand considering the "this situation must be matched" mind-set we are in at this point, but I do not believe it is pixie dust, however choose to skip it for now. See my conclusion at the end....
I think "superposition" is ther wrong term for this. If I could spell reciprocity, I'd say that it is a better word.
Digression, though minor: Superposition refers typically, to the application of two signals to a circuit and the resulting response being the

sum of the individual responses. no?

Now some meat I'd like to pursue...
>
> ...a 500 Ohm Source...you will never launch much power into a 50 Ohm
> system because it would immediately hit a reflective interface at the
> antenna connector.

There's a question I see here as to wheather the power was "launched" in
the first place and this may be part of the assumption (or set thereof)
which (my gut feel says) leads the logic astray.

> This means that a 500 Ohm source, when confronted
> by power going towards it from a 50 Ohm system will reflect most of
> that power (but how did we get this power into the system in the first
> place - Karma?) This, by design, will never happen in any transistor
> ham rig built in the last quarter century.

I think this is true...BUT let's ask this same question of a 5.0 ohm
source?? How would you carry this through Richard C? I submit that THIS
source CAN launch significant power down the line.

>
> ...snip non technical stuff
>
> The answer is the transmitter source Z is 50 Ohms at rated power.

OK, so now I see you are of the "Zs=50 ohms" camp.

> If
> a watt of power is chooglin' down the line toward it, that 50 Ohms is
> going to dissipate into a watt worth of calories. This can be argued
> with wave mechanics, or lumped circuit equivalents - doesn't matter
> because it's all the same calories.

All ok with me _IF_ Zs=50. I'm not convinced however. I have to think
more about the modern broad-band transistor PA to have an strongly arguable
opinion on this concept.

> Modern rigs can tolerate this...snip...
>
> === WARNING to the logic impaired, the following is a supposition ===
>
> Now, lets simply accept those answers that require the magic pixie
> dust

Uncalled for... I can make it work (so far though I am open) with the
electrical/electronic principles I think are true and work everywhere else.

> of total reflection from the transmitter. Fine, the mismatched
> antenna reflects some power, this power returns to the transmitter,
> the transmitter simple routes it ALL back to the antenna,
> round-and-round until the antenna finally radiates it. If this were
> true, what do we need tuners for?

I think the answer here is that if the transmitter can take the strange impedance it sees, then it isn't needed. Like Hanks 30L1 that, however, couldn't take it very well.
Furthermore, there is an implicit assumption here in your reasoning which I believe is key and leading to some error. There is an unspoken assumption that the power which makes it to the antenna after all the " round-and-round until the antenna finally radiates it" is the FULL output and I believe it AIN'T. It is that little dribble that made it into the line in the first place. a.k.a. the Tx is not generating the full output. I think this assumption is causing much trouble.

Unless, of course, I have been smoking the wrong brand.

>
>Are there other sources of plate glow?

Hi David,

Two methods come to mind: Calorimetry and Optical Thermometry.

Both are ancient methods, which means with patience and care you can
achieve very good precision and decent accuracy.

For the Calorimetric approach, simply enclose the tube inside an air
plenum with a good steady stream of air whose temperature is measured
going in, and coming out. To increase efficiency and accuracy, you
would want to build a diffuser into the stream to reduce turbulence (a
4 in diameter honey comb of straws cut 3 or 4 inches long would do
nicely). It would also be nice to draw the air from a relatively
stable temperature source and vent it away (no mixing).

You would then need to research the formulas to convert the heat gain
into watts. I won't go into that at this time.

As for the Optical Pyrometer (the actual term), this consists of a
binocular where one eye looks at the plate surface, and the other eye
is looking at a heated wire. An alternative is a monocular where the
eye looks at both at the same time (more accurate) where the wire
overlays the target image. You adjust the heated wire to luminescence
and when its temperature is equal to the temperature of the target,
the monocular view will offer the wire disappearing! In other words,
you have a bridge circuit and when both heated elements are balanced
the eye registers a null.

You would need a stable source of repeatable current settings so that
you can make differential measurements (the most precision) and
perhaps another target that you can directly measure heat and power
applied (the most accurate). For a wire, go to a junk store and buy
an old toaster. Each element is roughly 50 Ohms (not suitable for
precision RF however). Such a method can with care map temperatures
to within degrees.

I commend your desire to sit down to the bench and sweep away the
cobwebs of musty philosophies traded here.

Cec and Co., I keep telling you it's a waste of bandwidth talking about 'conjugate matches'. In the transmitter/transmission line context conjugate matches do not exist because nobody knows what the internal impedance of the transmitter actually is.

There's never any need to know. Of what possible use would it be if you knew it.?

Except provide a topic of conversation for this newsgroup. ;o)

That makes real waves tangible like real rocks. The wave particles
are just smaller. OTOH, "People who live in glass houses shouldn't
throw stones." is an intangible.

>>If they exist, they posses both energy and momentum.
>
> Bet ya can't prove it without first transfering it to something.

Optics, by Hecht is good enough for me. "It is possible
to compute the resulting (momentum) force via Electromagnetic
Theory, whereupon Newton's Second Law suggests that the *wave
itself carries momentum*. (all emphasis his, not mine) ... As
Maxwell showed, the *radiation pressure* equals the energy density
of the EM wave. ... When the surface under illumination is perfectly
reflecting, the beam that entered with a velocity of +c will emerge
with a velocity of -c. This corresponds to twice the change in
momentum that occurs on absorption, ..."

It's obvious that the energy in the TV ghosting wave makes a round-
trip to the match-point and back to the RCVR. That's obviously a
change in the direction of momentum of the reflected wave. It is
twice the change in momentum than if it encountered a circulator/
load and was dissipated.

> and out of an infinite impedance?

The question is a little misleading because the direction of the flow of current changes every half cycle and is transverse, or orthogonal to the direction of wave propagation. In a transmission line, the current flows through Z0, ostensibly, which is essentially the impedance from one conductor to the other at every point along the transmission line. Other than that, superposed forward and reflected waves behave just as you described, naturally.

2965. Polarization conversion

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-26 18:03:44 UTC
From: dariolq@yahoo.com
Message-ID: <c92ca4d3.0405261003.7ff0c26e@posting.google.com>
Source record: 94510

Hi everyone,
I've seen some very informative posts here and I'm hoping this
question will generate some more.

Does anyone out there know how to convert antenna field measurements
to linearly polarized components as well as circularly polarized
components?

I have a file with complex field data (E theta & E phi : real and
imaginary) and have been searching for a method to do the conversions
barring using poincare sphere concepts (they are non-intuitive as far
as I'm concerned. The linear conversion is pretty straight forward:

E_theta = sqrt(Re_E_theta^2 + Im_E_Theta^2)
E_theta_phase = atan(Im_E_Theta/Re_E_Theta)ï¿½correction factor for
quadrant placement

Same goes for E_Phi.

Does anyone know how to do it for circluar polarization?

Regards

Dario

Yes, I'm familiar with the subject. I've been familiar with it for a
long time.
However it is incorrect to infer that interactions between waves would
be the same as interactions between waves and matter!

> It's obvious that the energy in the TV ghosting wave makes a round-
> trip to the match-point and back to the RCVR.

It's obvious that the signal has taken multiple paths, at least.

> That's obviously a
> change in the direction of momentum of the reflected wave.

Perhaps. You're describing back scattering, which should exhibit a
Compton effect wavelength shift if true. But again, you're describing

an interaction with matter. Photons don't interact with each other in the same way they interact with matter.

From this I infer that Cecil believes that once the transient portion of the response has concluded you are in the steady state and no more reflections are occurring. Is this a correct re-statement of your belief, Cecil?

I paraphrase / quote the quote:
Power reflected from a mismatch back into the PA is not absorbed there.
He writes:
"when the pi-network tank is tuned to resonance, a virtual
short circuit to rearward traveling waves is created at the input
of the network. Consequently, instead of the reflected power
reaching the tubes of the amplifier, it is totally re-reflected
toward the load by the virtual short "

Hank, I'm sorry, but I believe this is not correct as stated. The word
"totally", I believe is misleading and contrary to what I think all will
agree. Namely that there MUST be SOME real part (although the true amount
is disputed here) to the Zout of the PA and therefore SOME power MUST be
absorbed there. I believe the point of contention truely is just how much
is absorbed and how much is reflected...

>> ...Also what happens in a transistor final with no pi?

AGAIN. Be careful that you DO NOT keep assuming that the full power is the
incident power. Incident meaning forward power or that which the
transmitter is sending toward the load. I have a real corker below. Be
careful. Do not try this at home, I am a professional. (yea, I know this'll
spawn all kinds of grief)

Tam sez:
> Henry,

> Tam/WB2TT

Tam,
Although I believe you have digressed somewhat, I will follow this path since it contains a closely related concept. You obviously have a pretty good handle on much of this (as others do, up to a point, and struggle to make their mental models fit the reality - or to make other's mental models fit theirs)...However, there is a paradox here which appears to be the root of this disagreement and your example hit it right on the head. You have some implicit assumptions here.

1) Zero volts across the resistor = (not said, but implied) the t-line acts like an open at the input end, therefore there is no current into the line which results in the zero V across R. V=I^2 * R. I think everybody will agree with this. (shorted 1/4 wave acts like an open and an open 1/4 wave looks like a short - mantra of all, no?).

2) Resistor current = zero therefore reverse traveling wave gets reflected toward the load end. The implication clearly is that with zero resistor current, no energy can be flowing out that way, so it must be reflected.

HOWEVER...
Been a while since I went to this depth and interesting to do so, though unnecessary, I will anyway...

If the input to this stub acts like an open, there can be NO current, thus no power entering, therefore there can be no forward wave, no reflected wave and no summation of waves to make the open in the first place and no need to re-reflect the reflected wave from the resistor who (or is it whom) has no current. This appears to be the root cause of this problem.
Now, we can say that (and I think it has been said) that it makes no difference how large these two waves (which cancel each other to form the open circuit at the stub input) can be any absolute magnitude. 1 amp 10 amps 100 amps doesn't matter - they cancel. So what are they really?
There are two things to consider as you work out how you will resolve this paradox in your mental model.
1) I believe the most important -- If the Z looking in to the stub is high, how can you send a large amount of power down the line. If you say it is an infinite Z then you have a really big problem explaining how it got there in the first place.
2) There is a tendency to assume that the forward power is the same power as when the load is not a short, but Zo.

Interesting puzzle, but I don;t need to go further. At some point you must 'believe' something and I can comfortably stop there...for now.

Oh well...

Cecil, W5DXP wrote:
"Anything about dissipationless resistances or negative resistances (in "Transmission Lines, Antennas, and Wave Guides")?"

On page 73, the characteristic resistance of free-space is defined as the sq rt of the permeability of space devided by the dielectric constant of space. The units are henries/m and farads/m. The solution is a voltage to current ratio of 376.7 ohms, or 120 pi ohms.

As free-space is a perfect (lossless) medium for radio waves, it is a dissipationless resistance.

On page 13, the characteristic resistance (Ro) of a transmission line is given in formula (14.3) as the sq rt of L/C, but this is an approximation for low-loss lines as there are no perfect lines.

Negative resistance is a gain instead of a loss. The authors of "Transmission Lines, Antennas, and Wave Guides" were writing for WW-2 officers being trained at Harvard University in radio and radar. The phone system was then using some "negative resistance repeaters" but neither these nor "active antennas" were big at that time. You can only make up the loss in a two-wire phone loop with amplification. Any more gain and the loop "sings" (breaks into oscillation).

Best regards, Richard Harrison, KB5WZI

There is no current in the steady state. The steady state voltage is
independent of source impedance, which affect only how long it takes to
reach that. I ran a simulation on this, and you can see that as the voltage
builds up, the current decreases

I don't know of any such instrument.

One problem is the very definition of far field. It's a region in which the properties of the radiated wave approach their final values. Some of the characteristics of these final values (that is, the values the wave approaches at very great distances) are (for propagation in air):

-- The field strength decreases inversely with distance
-- The ratio of E/H = the Z of free space (about 377 ohms, purely real)
-- The field has no component in the direction of travel

All these characteristics are approached as a limit, and the distance at which one or more are "close enough" is strictly a matter of definition and the particular application. It's at that somewhat arbitrary point that you're said to be in the far field.

You can devise instruments to measure any or all of these properties, although I'd think doing it with any sort of accuracy would be beyond the reach of most amateurs. But if you did, you'd still have to decide, on the basis of the measurements and your own criteria, where you'll draw your own particular line.

======================

Why must engineere resort to quoting from their worshipped Guru's who are hardly more likely to be correct than they are themslves.

In all probability the recipient of the advice does't have a copy of the sacred text. If he did he wouldn't be asking the question anyway. And it must be extremely rare for anybody to spend weeks attempting to find a copy. He knows he will have lost interest long before he finds one.

Do engineers these days, in their daily work, depend entirely on the 'gospel truths' to be found in text books on their extensive book shelves without much understanding of what its all about? It's a recipe for time-wasting errors!

Or are they content to obtain money under false pretences?

Sorry about the diversion. I'm in that sort of mood tonight. I'm on Pinot Noir 2001, red - a product of Romania, bottled before Romania became a EU member. But it's no worse than the Italian, Spanish, French, or even the Californian plonk!

Never sampled a 6-shooter, John Wayne, Texan vintage.

Hello to all. I continue to return here as antenna's are the hardest thing to figure out. We can end the cw argument by testing antenna knowledge hi hi! Anyways, I have a rock mite 20m qrp that I built and am giving it a go with a random wire hooked to an mfj 901b tuner. I am using 22 gauge stranded at about 16 feet. The tuner has a ground wire as well. Here is the trick . . . I have a buzz in the headphones only at certain times. I can move the headphone wire around and it changes the tone and amplitude of the buzz. In fact it sometimes goes away all together. However, when I put my hand on the final in the altoids can, it also lessons it as well as when I put my hand on the can. It sounds like a ground problem but not sure how to fix it. I tried different grounds but to no avail. Another problem I am having is the swr meter I have will not do less than 5 watts(RS) so I am trying to wing it with the tuner and try to get the highest noise level. Once again though, if I turn the inductance past d/e I get the hum again. Also if I turn up the antenna adjustment, the buzz gets worse. I know this is a long one, but I am hoping someone can help me out.

So far as using a field strength meter for tuning up the transmitter is concerned, you will not notice the slightest difference between near and far field. There is none. They are both produced by the same transmitter.

You'll get different strength readings at different distances from the antenna, and in the near and far fields. But they'll all stay in proportion as you tune your linear, so it doesn't matter where you put your meter. The only exception is that you need to put the meter far enough away from the linear that it won't be responding to radiation leakage from the linear itself, which could be coming from the tank components or parts of the circuit ahead of it. You could check this by seeing what your field strength meter indicates when the linear is feeding a good dummy load. If it's a significant part of your reading when driving an antenna, you need to move the meter.

>a buzz in the headphones only at certain times. I can move the headphone
>wire around and it changes the tone and amplitude of the buzz.
Hi Greg, First of all I have never used a rock mite, but I will just give
some thoughts. If the receiver is a direct conversion type, they are bad about
picking up 60 hz hum. Does the buzz sound like 60 or 120 hz hum? The finger
touching the final increasing the hum should be a clue.
The antenna may or not be a problem. QRP swr and watt meters are not common,
you may have to look at building one.
Consider using a 20m coax fed dipole, only 33' feet long, and will work ok
20' high. This is balanced, to a degree, and will not require a tuner
Get an antenna analyzer (MFJ 259B ect.) and make sure the impedance at the
tuner input is 50 ohms, assuming that is what the rock mite wants to see.

>Why must engineere resort to quoting from their worshipped Guru's who are
>hardly more likely to be correct than they are themslves.

That's easy, because most of the time we have no other choice. When designing circuits, antennas, troubleshooting, or talking to newsgroups, we have to rely on other's research. There is no way we can experimentally verify all the data sheets. charts, graphs, computer programs ect. that are available.
Quoting the last 100 years of antenna research, from worshipped Guru's should not be a bad thing, because most of us will never have the opportunity to prove them incorrect. I assume many of the Guru's did the research.
Reg, I am sure you have found numerous errors in Guru's texts, and have tried to point them out to us. But you cant't just go out in the back yard and burn all those books:-) Who would we then quote?

Thanks for the answers. I even got a personal reply from someone with some Pinot across the pond confirming the above.
No clear boundary, no differnce and it's OK to have the FS meter in the shack. Now why can't I find out this quick and easy if the final in a Tx is dissipative or non-dissipative to reflections?

Direct-conversion receivers are rather notorious for being subject to
a phenomenon called "tunable hum".

According to what I've read in "Experimental Methods in RF Design",
the root cause of this problem is local-oscillator radiation and
modulation. The D-C receiver has an oscillator running at all times,
which is being fed into the mixer. Mixers have a finite amount of
isolation between the L/O port and the RF-in port, and some amount of
the L/O power is coupled back out through the RF-in port. In a simple
D-C receiver, this L/O power can be coupled right out to the antenna,
and radiated. This can cause two effects:

- It's audible on other receivers in the area, as a "birdie" at the
receiver's LO frequency.

- It can be coupled into nearby power wiring, and mixed (in the RF
sense) with the 60-cycle powerline waveform and the waveform's
harmonics by nonlinear devices hooked to the power line - i.e.
power supply rectifiers. This mixing (which is in effect a
modulation) can create RF sidebands, located 60 and 120 and 180 and
240 etc. Hz on either side of the local-oscillator frequency.
These sidebands radiate out through the power wiring, are picked up
by the antenna, and are demodulated by the D-C receiver's mixer.
In sum, then, you end up hearing powerline hum and harmonics in
your 'phones, even if the D-C receiver is powered by batteries and
has no connection at all to the power mains.

The best fix for this is to include an RF preamp or buffer between the
receiver's antenna and mixer. The benefit doesn't come from the
preamp gain - it comes from the additional isolation that the preamp
adds to the circuit, thus blocking the L/O leakage from the mixer

before it can reach the antenna and be radiated. As best as I can recall (I don't have the schematic handy) the Rockmite does not include such a preamp.

If your Rockmite isn't battery powered, try that. Also, try using a balanced antenna, located further away from your listening area (and from power wiring, etc.) - this may reduce the degree to which the L/O leakage couples into the power lines and creates sidebands.

I do hear some small amount of buzz/hum on my Rockmite, even when battery powered and even when hooked to an outdoor inverted-V dipole located some distance from the building and from any power wires.

Simple D-C receivers can also be subject to strong-signal overload and intermodulation. It's not uncommon to hear AM broadcast-band signals on a Rockmite or Pixey or similar, due to strong-signal overload of the mixer. There's a simple modification available for the Rockmite which greatly reduces this problem... if I recall correctly it's a single resistor, placed in parallel with the diodes located just before the mixer. It's possible that your hum/buzz is coming from intermodulation from a strong local RF source of some sort - if so, this mod might help matters.

> Another problem I am having is the swr meter I have
>will not do less than 5 watts(RS) so I am trying to wing it with the tuner and

>inductance past d/e I get the hum again. Also if I turn up the antenna
>adjustment, the buzz gets worse. I know this is a long one, but I am hoping
>someone can help me out.

Unfortunately, the increase in buzz may indicate that you're establishing a better match with the antenna... you'll transmit more effectively, receive more effectively, but also leak the local-oscillator power more effectively.

If you want a tuner better suited to QRP operation, I can recommend the Norcal QRP (now AMQRP) BLT kit. It's a simple Z-match tuner, good for up to about 5 watts, capable of feeding balanced antennas or (with one additional jack and a switch) coax-fed antennas, and including a simple resistive-bridge SWR meter which provides a useful tuning indication with only a few milliwatts of power. It's a nice match for the Rockmite.

http://www.amqrp.org/kits/blt/ for the kit. If you've got a well-stocked junk box you might already have everything you need to build a similar design. Least-common component is probably the little plastic varicaps - you could certainly substitute broadcast-band air variable caps if you have a couple handy.

Hey guys,
Jog my memory; but don't some power tubes have a high value negative plate resistance under some bias conditions and will oscillate under no load conditions if external losses are low.
The 4CX250 family comes to mind.

Cecil,
I think it is more instructive to turn on a DC voltage at t=0, rather than a sine wave. In either case, the voltage builds up step wise, with smaller and smaller steps until you don't see them.

Richard,
I believe Edison was talking about the Synchronous Impedance of an
alternator. That measurement is based on the short circuit current of the
machine, and limited by the leakage inductance; purposely made large for
self protection. As for pertinent numbers, a 2300V 1000A alternator has an
effective series resistance of about .05 Ohm. That is feeding a load of 2.3
Ohms.

==========

There's no need to. Inevitably, 99.9 percent of data to be found in books does not match up to the exact problem in hand. And what is in hand is VERY exact. Very early in one's career one realises this and soon discovers it is largely a waste of time 'researching' the literature for details. There's too much of it. It is more expeditious to have confidence in one's ability, to go back to first principles and THEN concentrate on the details in and - which are NEVER to be found in the books.

The best engineers don't have time to write books - except perhaps for short, simple ones which educate by concentrating on first principles. A relatively few number of such books or papers are needed. Nearly all of them have already been written. Such as Shannon's beautifully concise paper on Ball-packing.

==========

> Quoting the last 100 years of antenna research, from worshipped Guru's
should
> not be a bad thing, because most of us will never have the opportunity to
prove
> them incorrect.

==========

But good engineers accidentally find them incorrect all the time. It forms part of their normal wasted time. Anybody who worships a book has only ever read it (e.g. not built the circuit) - he has never used it in anger. It has to be admitted that finding more than two errors in a book (not counting obvious printing errors) is enough to destroy its sacred properties.

==========

> Reg, I am sure you have found numerous errors in Guru's texts, and have
tried
> to point them out to us. But you cant't just go out in the back yard and

> all those books:-) Who would we then quote?

==========

I once quoted (second hand) from a text book on this newsgroup. But it was in an ironical context. Probably nobody noticed.

I possess remarkably few books on radio enginering. One of then is a treasured 1937 copy of Terman's Radio Engineering. I may refer to it once every few years because of its comprehensiveness. I have a poor memory. But I wouldn't dream of using numbers from it in anger without checking from first principles they are in the right ball park. I remember first principles. They are so simple and can be expressed in plain English.

But I could not bear to see books of any sort burned! Carry on quoting Kraus who I am a little familiar with via this newsgroup.

The bottle is finished. Good Night.

DC doesn't tell us anything about a 1/4WL shorted stub which is a
network problem, not a circuit problem. The net current at the mouth
of the stub is close to zero while the voltage is at a maximum. At
the short at the other end of the stub, transmission line theory holds.
The voltage is close to zero while the current is at a maximum. Now
exactly how can maximum current be flowing through that short if
no current is flowing into and out of the stub. Hint: it can't!

The forward current and reflected current cancel at the mouth of
the shorted 1/4WL stub. However, they add in-phase 1/4WL away at
the short, maybe to many amps of RF current at the shorted end.
Since there is no physical impedance at the mouth of a stub, nothing
except superposition of forward and reflected waves happens there
and nothing except a virtual impedance exists there. All of the action
is at the shorted end of the stub where there exists 100% reflection.

3016. Re: rock mite 20 qrp random wire ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-27 01:41:54 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <10bahr8g7bm368f@corp.supernews.com>
Source record: 94454

Dave gave some good suggestions, but let me add one more. You might be hearing detected video from a strong TV station. Years ago when I was testing audio amplifiers for the little "Optimized" transceiver, I was driven nearly to distraction by that until I finally figured out what it was. In my case, the headphone wire was the main antenna for the video, and a good bypass with very short leads right at the headphone jack cured it. But in your case it could be getting in via the antenna or power supply leads as well. You can bypass the power supply leads, but it takes a little knowledge and care to let HF through the antenna lead while effectively stopping VHF or UHF TV.

Winding the power supply and headphone leads a few turns on ferrite toroids close to the rig can also be very effective. A good type of ferrite to use is type 43, which is common, although most other kinds will work fairly well. You'll probably want to use separate toroids for power supply and headphone, for convenience. Keep the two conductors together as you pass them through the core.

Here's how to identify detected video. Hold perfectly still, and see if the buzz changes. The sound of video will change with the transmitted picture. If you can correlate the changing sound with the picture from a local channel, you have the smoking gun. But even if you can't, a buzz that changes rougness and loudness while you hold still is pretty good evidence. If you have a 'scope, you can identify video by using line triggering. Video will look like a pattern that slowly scrolls by, taking about 20 seconds to drift a full "cycle".

I don't own a R7000 but there are many user reviews of this particular antenna on www.eham.com. It appears from the reviews that the traps may be the problem. Possibly, water is getting into one or more of the traps.

I just did the simulation again, and you are right. For a 1V signal feeding
a 50 Ohm line through a 450 Ohm series resistor, there is 20 ma of
current flowing through the short. Don't understand why I didn't see it the
other time. There is 0 current through the 450 Ohm
resistor.

Hi Andrew,

>>a load capacitor value of 250 +/- 10pF (-j80 ohms @ 8 MHz) was found to produce a
>>minimum in the total voltage across the load.
What was the voltage?
>>Also, as capacitance was increased over the range 100-700pF, the voltage across the load
resistor
>>increased monotonically.
What were the voltages?
>>The latter is easy to explain (it means the source reactance is positive, and
>>smaller than +j28.4 ohms), but the former is beyond my ken.
as the capacitive reactance falls, you note the voltage climbs, this
hardly requires an inductance to explain this. Simple divider action
serves quite well. You have since revealed the inductor buffered
output, but the data is still pretty skimpy to bless it as the major
contributor to source Z.

What are you using to measure this voltage?

Left Circ E = 0.5 * (Eh + j Ev)
Right Circ E = 0.5 * (Eh - j Ev)

where Eh and Ev are complex horizontal (phi) and vertical (theta) linearly polarized E field components respectively. Left Circ E and Right Circ E are of course also complex.

You can find this in just about any antenna text. A text would probably be a good investment if you're going to be digging into theory at this level.

Install a Bird wattmeter at the 450 ohm resistor and you will read
forward power and reflected power. The *net* current through the 450
ohm resistor is zero. The forward current is not zero. The reflected
current is not zero. Their magnitudes (10 ma?) are equal and their phases
are 180 degrees from each other so they cancel to net zero current.

If we take the forward current at the 450 ohm resistor as a reference of
10 ma at zero degrees, the reflected current will be 10 ma at 180 degrees.
Those two current signals add up (superpose) to zero at the resistor.

There is no net current flowing from the source, but there is net current flowing through the short during steady-state. Where does that current come from? It comes from the in-phase addition of forward and reflected current. The voltage goes to zero and the current doubles at a short. The zero net current from the source comes from the out-of-phase addition (subtraction) of forward and reflected current.

This is where that darned definition comes into play. By definition, the reflected current is being 100% re-reflected and the source is delivering zero current or, in a system with losses, is delivering only the amount of current needed to offset the losses.

We can argue whether the reflected current makes it back into the source or not. But there is no argument that reflected current is originating at the short in the 1/4WL stub because it can be easily measured. Forward current and reflected current are very close to equal magnitudes all up and down an efficient stub.

Very clear and concise. I am persuaded that once circulating current is established, only the current required to supply losses is drawn at the mouth of the shorted 1/4-WL stub.

No, no, no. That is a re-statement of the other side of the argument
from mine. I often use devil's-advocate type arguments.

The definition of steady-state by the other side is pure unvarying
sine waves with no noise and no modulation. Then the reflections
sorta disappear into a steady-state mush of standing waves. A
modulated TV signal, according to their argument, is not a steady-
state signal. Within this steady-state mush of standing waves, energy
never makes it from the load back to the match point. Apparently,
because of the uncertainty principle, reflected energy doesn't
actually exist anywhere until it is radiated or dissipated, i.e.
its probability wave collapses.

I have challenged them to produce a standing wave without a rearward-
traveling wave but nobody has been up to that challenge.

Steve,
I think there is an analogy here to a high Q resonant parallel tuned
circuit. It takes very little to exite this, but there can be large
circulating current in the L and C.

BTW, on my shorted transmission line: I had looked at the current on the
transmission line - at the wrong end of the TL. There is current at the
shorted end, none on the source end in steady state. Didn't even know the
program was smart enough to know the difference. Seems to me that once you
have put all the energy into the TL that it can store, you don't have to
supply any more energy (?)

Steve, what you are missing is that the match point is not at the transmitter terminals and reflections indeed do flow into the transmitter terminals. The match point is between the tube finals and the input to the pi-net tuning section. There are zero reflections between the input of the pi-net tuning section and the tube finals. This is what Walter Maxwell was saying. The "input of the network" that he is talking about is the wire between the tube finals and the built-in pi-net tuning section and, indeed in a properly tuned transmitter, there will be no reflections at that point which was commonly known as a "Zg-match point".

All of Walt's writings assumed a Zg-match internal in the tube transmitter at which all reflections were canceled. We hashed that out about 20 years ago. That's when I first communicated with Walt through snailmail.

Dave, N3HE wrote:
"Picture an alternator delivering rated current into a resistance:---."

Reactive current adds to the total. It often comes from many lightly loaded induction motors supplied by the power system.

Fortunately, the power factor of a synchronous motor can be varied over a wide range by control of its excitation. Often, unloaded synchronous motors are connected to a power system for the sole purpose of controlling power factor. An unloaded synchronous motor can make a really large variable capacitor.

Best regards, Richard Harrison, KB5WZI

Load voltage lies in the 5 to 20 volt peak range, depending on the power
setting.
This minimum represented about a 15% dip.

> contributor to source Z.

Agreed, but if I keep increasing the load C (decreasing the capacitative
reactance), I will see a peak in the voltage across the load resistor, which
will only happen if a conjugate match is occurring.

> What are you using to measure this voltage?

A scope probe set to 10x, which has an unmeasurably high DC resistance and a
capacitance of 22 pF (measured). It's a good idea to use the 10x, not 1x,
setting, since the latter contributes about 80 pF, and will change the AC
response of the circuit.

Best,
Andrew

It's a very condensed verion of the reams of stuff that some posters have
posted over the past year. In particular, when I tried to introduce noise
and modulation to prove my point, I was told that noise and modulation are
not allowed during steady-state.

I recently acquired a tower that is thought to be made by Rohn. I got some information on 25G and 45G towers from www.rohnnet.net but mine seems to be somewhere between these sizes. It measures ~13.75" between centers of the legs and the legs are 1.25" diameter. It is galvanized steel and otherwise resembles newer Rhon towers. It's probably 25 years old but is in excellent condition. Any info is appreciated.

No/Yes. The "two" signals are those I described, the one from the
source as source and the one from load as source. This is the
convention of Circuit Analysis by Mesh or Nodes. Kirchhoff mandates
all voltages will sum to zero. The summing is a solution of
simultaneous equations - Superposition.

> I think this is true...BUT let's ask this same question of a 5.0 ohm
>source?? How would you carry this through Richard C? I submit that THIS
>source CAN launch significant power down the line.

And here we come to issues of initial conditions and their variation
to force a conclusion. Namely, the unstated condition is how much
voltage is available? SWR is the diagnosis, and absorption of power
is the issue. Launching of power also suffers from the same
condition, but it would be well enough to examine the reflection
first. Launching problems is a sidebar.

>> The answer is the transmitter source Z is 50 Ohms at rated power.
>

>
> All ok with me _IF_ Zs=50. I'm not convinced however. I have to think
>more about the modern broad-band transistor PA to have an strongly arguable
>opinion on this concept.

It is a convention of design that is covered in many design texts.
Academe takes this (Zs=50) for granted so much so that it is rarely
discussed. Even here I have references (Academic) that make this
point explicit and I have offered them here in debate.

As I have never stated this, you have to answer for the conflict that
follows.

> It is that little dribble that made it into the
>line in the first place. a.k.a. the Tx is not generating the full output.
>I think this assumption is causing much trouble.

This begs the question: What is the full output? A battery sitting on
the shelf is not generating its full output is a simple example, but
does not tell us what that full output may be. This is the problem of
definition by negatives.

It is not generating:
1W
nor
10V
nor
100ï¿½C
nor

1 H.P.

Was it ever capable of those generations in the first place? Under what conditions? Saying what is "not" has no useful information here.

If we are discussing what happens to power impinging upon the source, it should be obvious that if that power is OUT OF PHASE trouble follows in the form of currents. If that power is IN PHASE trouble follows in the form of potentials. Trouble is proportional to the degree of mismatch. Trouble arrives through the model of waves, trouble resides in the model of lumped equivalent circuits. It is the same trouble either way in the form of heat. Choose your poison because equipment manufacturers have built-in foldback mechanisms and advise you to use a tuner for good reason.

>Unless, of course, I have been smoking the wrong brand.

It will be available over the counter in British Columbia soon.

> (TV signals are of course always changing.)

You can prove your point only by demonstrating an RF storage
battery in which RF energy stands still.

Got news for you, Jim. RF energy *always* flows because it *cannot*
stand still. It flows in one direction in a transmission line, at the
speed of light, until it encounters a physical impedance discontinuity
at which point reflections occur and some or all of the energy changes
directions, but always moving at the speed of light. ExH is the power.

Of course, you are talking about *NET* energy above. Forward
and reflected energy continue to flow unabated. RF component
energy has no choice except to flow at the speed of light. If
there doesn't exist a match point to turn the reflected energy
around, it *will* flow into the source. That you subtract the
reflected energy from the forward energy at the source output
to obtain the "generated energy", is just a math shortcut and
bears no resemblance to reality. It is a definition created by
man for the purpose of avoiding a very complicated problem.

It is akin to the problem of absolute motion in space-time.

It follows that when you have the same bank balance at the beginning
of the month and the end of the month, you tell everyone that you
had no debits or credits during that month. Again, you forgot to use
the word "NET".

>
> 73, Cecil http://www.qsl.net/w5dxp

Cecil,

I don't plan to enter this endless argument about transmission lines, but there are a couple of points you might want to consider.

* Steady state simply means that a phenomenon has no inherent reference to its time of origin. One cannot observe a steady-state wave and determine any clue about when it started. It contains no absolute time markers. A transient, on the other hand, contains direct reference information about when it was formed. There is no requirement that the steady state phenomenon is a simple sine wave.

Many problems in math, science, and engineering exhibit both transient and steady state solutions. It is not clear why there is any confusion at all in this thread.

* Standing waves don't require the pre-existence of traveling waves. A straightforward application of Maxwell's equations with appropriate boundary conditions for the physical environment will lead to standing waves directly. Check out one of your recently quoted favorite authors, J. C. Slater, and look at some of the resonant cavity stuff. Most definitely standing waves, but you will find lots of complex Bessel functions and darn few traveling waves.

In virtually every transmission line situation proposed on RRAA, whether tuned antenna feed lines or quarter-wave stubs, the transmission line is resonant. It is possible to consider the resulting standing waves as the sum of two traveling waves, but it is equally valid to consider the transmission line as a simple resonator. The physically measurable instantaneous voltages and currents are precisely the same whether one considers oscillation from capacitive to inductive energy storage in the line or the sum of two counter-traveling waves.

You often refer to wave-particle duality and to the use of S-parameters instead of lumped circuit analysis. The world of science and engineering is absolutely filled with this sort of dual description for physical phenomena. In many cases one approach will be more convenient or more intuitive, but that does not make the dual approach less valid.

There's more than one way to skin a cat.

>transmission line impedance, right?

Where does it say that!? You had to guess, so that makes it less than
explicit, and now we have two questions to answer instead of one. Is
this accumulation of questions a linear or power progression? Web
debate is notorious for arguing the color of the table, then its
shape, then the number of chairs... before you get to the debate at
all.

If this posting had been headed with the answer "I don't know -
but...."

>As I stated before (with spelling corrected):
>
>Get this MPT theorem blockage out of your minds... It is a synthetic
>restriction.

I didn't infer it, much less explicitly address it. I made a
statement of fact, and it is quantifiable and measurable. Whatever
occurs as a consequence of it is entirely another matter.

Stands to reason. Intentionally absent from the steady state are noise,
modulation, transients, and any other perturbation. It would be kinda
like opening the lid of an adiabatic chamber in order to see if the
internal temperature stays constant.

I have some of the same tower. It is known as Rohn "35" or "HW". It was
apparently made for Motorola by Rohn.

You can find out more by searching the Towertalk archives for "Rohn 35"
http://lists.contesting.com/archives//html/Towertalk/

Pick the ONE and SAME power setting. What was the voltage across the
load resistor for:
100pF
200pF
300pF
...
700pF

This is a violation of terms. Just what constitutes the generator?
At one time you say the combination of the cap-resistor is the load,
hence the source is described ACROSS this series. THEN you isolate
the resistor which pushes the cap back into the source.

You originally asked for the complex impedance of the source, but if
the source contains a variable cap, this makes determination rather a
moving target.

In the world of metrology (folks who measure this stuff for a
living), you have an immutable boundary called the plane of the
source. On one side is everything that can be attributed to the
source and everything on the other side can be attributed to the load.
If there is a transmission line between, then you have two planes, the
plane of the source, and the plane of the load. Everything to the
right of the plane of the load (thinking in a left-right progression)
can be attributed to the load. Between the two planes is a transform.

The plane of the source is commonly the output connector, the plane of
the load is commonly the input connector. Things in between like
tuners, SWR meters, Lines, dividers, splitters, duplexers... are
transforms.

It is perfectly justifiable to make a component like a tuner resident
within (and behind) either plane, but once you do that, it is
considered bad form to go tweaking it and maintain nothing has
happened to the source/load.

>> What are you using to measure this voltage?

"Steve Nosko" <suteuve.nosukowicuz@moutouroula.com> wrote in message news:<c92tov$1kv$1@newshost.mot.com>...
> OH! NO! Vortex vs. Bernoulli

Actually, it's Circulation vs. Newtonian vs. Bernoulli -- all three are different mathmatical means of describing accurately and precisely what happens when a airfoil produces lift. Actually each is simply a different way of expressing exactly the same thing, but none of them translates well to a real-life understanding of the concept. One of the problems is that causes and effects get confused and oversimplified by the math.

Much the same with reflections, transmission lines, and impedance matching. While reflections do indeed exist on transmission lines when mismatched to a source or load, they simply create standing waves. Standing waves create non-optimum impedances depending on the characteristics and length of the line. These impedances interact with source and load impedances in very predictable and calculated ways. Efficiency of power transfer is then determined by optimizing the matching of these impedances. Optimimizing impedances then eliminates reflections --- a circle of causes and effects.

Mathmatically, it's more expedient to skip much of the in-between cause-and-effect stuff, and jump directly to describing the entire process as a direct relationship between reflections and power transfer -- which causes problems when attempting to visualize or explain the process -- because that's not the way it really works. It's not quite that simple and direct.

A standard SWR meter is a good example. It can't conveniently measure reflections OR standing waves, so it measures mismatch. Since everything is directly related, it could be said that it measures reflections -- but it really doesn't. So, it doesn't really matter unless you try to understand how the meter works in terms of how it measures reflections or standing waves.

Cecil,

Sorry, you are not paying attention.

I gave you a reference that is full of such examples. Another reference you have quoted on numerous occasions is "Transmission Lines and Networks" by Walter Johnson. Take a look on page 164. He gives a description of standing waves and then comments, "One can imagine two oppositely traveling waves, . . . "

Note that he uses "imagine", not required, essential, or any other mandatory word.

I do not claim the use of superposed traveling waves is wrong. However, it is merely a mathematical trick, not unlike describing a square wave as a summation of Fourier components. This is very commonly done, and it is often very useful. It does not mean that mathematically derived sub-components are somehow more valid representations of nature than the original form.

Couldn't possibly be that you don't understant, huh?

Someone has shot a bullet into an iron wash pot. It ran around
the rim of the pot and changed directions by 180 degrees. Just
as it was changing directions, another bullet was fired from
the same gun. The returning bullet has less energy than the
second bullet. Therefore, the net energy is away from the gun.
Want to stick your head in front of the ricochet bullet
to prove that component energy doesn't matter?

WARNING! I use the sinusoidal steady state assumptions for this explanation, this means that all reflection transients have died out and the input signal is not changing. These are generally good assumptions for general use that does not depend on signal changing on a time scale similar to the reflection period, like radar or fast scan tv.... for cw, am, and even ssb in amateur sized systems these are generally very good and yeild answers that are more than adequate to answer problems like this.

given the above its very simple. look at the coax connector as if it was a connector on a black box, there are no reflections. period. the input of the black box looks like a simple linear impedance.

the procedure to find out how it affects your pi network is this: use your favorite circuit modeling program and model the linear and output network to whatever degree of detail you see fit. attach a load of 50+j0 and determine currents and voltages in the matching network. (note that you will have to include real world losses in the inductors and capacitors if you want to calculate power dissipation in them). change load to however bad a condition you want to model and compare currents and voltages to the 50 ohm case. this will show you if more or less power is lost in the matching network. if you have modeled a tube or fet with real world parameters it will also tell you if it's dissipation goes up or down.

You know that I know, "imagine" is just an expression authors use in the remote event that there might ever be a standing wave without a forward and reverse wave. All I am asking is for you to provide just one example where standing waves are not caused by forward and reverse waves.

You guys mealymouth all around that challenge but NEVER have provided a decent answer. If you are not going to provide that requested example, IMO, you have nothing to say worth listening to. So Gene, please, put up or shut up, and please stop jerking us off.

Hank, when reflected current flows backwards through a pi-net loading
coil, some of the reflected power is dissipated as I^2*R losses in
the coil. Other than that, a properly tuned pi-net causes a match
point that reflects all the reflected energy back toward the load.

If a match point exists in a ham radio antenna system, no reflected
energy will reach the source. This is the great majority of amateur
radio systems and no-reflections-at-the-source is the goal of every
ham. The thing that you are worried about is the unusual case where
reflections are allowed to reach the source.

Yep, pretty good for answering the transmitter question. Not so
good for answering the question of what happens between a tuner
and an antenna. One must remember that with your method, one is
dealing with virtual impedances, i.e. voltage to current ratios,
which are themselves a result and not the cause of anything.

Cecil,

Wow! Struck a nerve. Must be close to the truth.

I have said repeatedly that the alternative technical descriptions co-exist. I have never said that one "causes" the other. That would be folly, since we are dealing with math models, not physical cause and effect.

Let me turn the arrow back to you.

Give us one example where forward and reverse waves "cause" a standing wave, and then prove that it's not the other way 'round.

I am not aware of any credible technical writing on the subject of cause and effect in these matters, so I am anxiously awaiting your answer. (Hint: Don't waste your time.)

And as to "shut up", yes, I will now do that.

Until next time . .

Bullets and radio waves? No. Matter behaves differently than do
electromagnetic waves. I'm quite confident about that.

Too easy, Gene. Do a web search. *ALL* demonstrations of standing waves on the web using javascript have the standing wave *caused* by superposition of a forward wave and a reverse wave. There are hundreds, if not thousands, of examples. If standing waves could exist without forward and reflected waves, don't you think someone of your own steady-state cult would have provided an example by now?

Again, I challenge you (or anyone else) to provide an example of standing waves in a transmission line without forward-traveling and rearward-traveling waves. Is just one example, one tiny example, of what you are asserting, too much to ask? Apparently it is.

So what? Some matter behaves differently from other matter. Hint: Jim,
here's a heads-up for you. You must be omnipotent in order to prove that
you are omniscient. I hope you are up to that task.

My challenge still stands. Please provide a standing wave without a
forward-traveling wave and a rearward-traveling wave. If you can't,
at least send me a joint of whatever you are smokin'.

I would like to operate a 5 watt 151. MHz mobile transceiver into a ball and spring low band whip antenna similar to the old bumper mount CB antennas except that the antenna would be mounted directly to the top of the rear fender of a large 1960's American car and needs to be around 5-7 feet high. I need to use this type of antenna to give it the appearance of an old police car.

Is it possible to do this effectively without damaging the transmitter. I realize that this is an amateur radio board but I thought that amateurs would be the best group to ask. Thank you.

Hi Bruno,

MURS allows only 2W effective radiated power, not 5W going to an antenna. Further, this is into a simple antenna. Yeah, I know, yours seems to be a simple one, however as long as it is (5-7 feet high), it is both a poor match (almost no power out), and would have gain (a power multiplying factor) if you did match it (making it more powerful, hence the term "effective" radiated power). Even more unfortunate is that this gain (and most sensitivity for receiving) would be up into the sky! This is like drawing three cards to an inside straight: antenna too long, poor match, deaf too.

Now, this sounds like a lot of contradictions I am sure. The simplest antenna would be roughly 18 inches tall. Use the AM radio antenna for that, use a legal transmitter, and put up your buggy whip to impress the buddies. As an alternative, the antenna length you are describing is quite close to those used in the CB bands which would work just as well, if not better (as long as who you talk to use the same bands).

By the way, are you located near Norwalk Connecticut?

> understandable write up.

If you read Chapter 13, "RF Power Amplifiers and Projects", in the
2004 ARRL Handbook, there are pages and pages of discussion of
matching plate or transistor output impedances to 50 ohms output and
not once do they ever refer to output networks dissipating or
reflecting reflected power. Not once. It's always a matter of simply
matching one impedance to another to provide the highest power output
consistent with required linearity, while staying within the
amplifiying device's ratings.

Transmission lines have reflections; output matching networks and
tuners don't. The reflections on transmission lines don't make it past
the end of the transmission line -- that's where the reflections take
place. Beyond the end of the transmission line, the reflections are
seen as mere impedances created by standing waves, which are created
by reflections, assuming mismatch.

Hi Al,

Watch it, this is a heresy. ARRL is certainly not the end-all be-all of design advice, but given these points are confirmed by professional design guidelines and technical papers, one should be able to trust it as a source written at a level suitable for amateur introduction.

>and not once do they ever refer to output networks dissipating or
>reflecting reflected power. Not once.

However, absence of discussion does not necessarily mean there is an absence of concern.

>It's always a matter of simply
>matching one impedance to another to provide the highest power output
>consistent with required linearity, while staying within the
>amplifiying device's ratings.

Simple logic dictates as much.

>Transmission lines have reflections; output matching networks and
>tuners don't.

Simple logic does not allow this however. However, verifying this property would be rather a challenge.

>The reflections on transmission lines don't make it past
>the end of the transmission line -- that's where the reflections take
>place.

True, but only insofar as the tuner is adjusted to offer a conjugate.

>Beyond the end of the transmission line, the reflections are
>seen as mere impedances created by standing waves, which are created
>by reflections, assuming mismatch.

Again, true after a fashion, but the distinction is only a matter of point of view. Wave mechanics/lumped circuits give the same result.

I am hoping someone here can guide me to what the heck is wrong with my antenna system. Here is what is going on. Frist, I know neight of trhese antennas are very good phtsically or functionally BUT they both can be tuned down to a very accepatble SWR. However, using eithe my Icom 706 G OR my old Kenwood 440 AT even with a good SWR <1.5 or better I get a terrible audio report. I have monitored the audio using the other radio and it sounds like a warble variable picth sounds as I speak. sounds like very high over driving but I have that all turned down. I have used an MFJ 949e tuner and even let the Kenwood with auto tuner tune the antenna same results .. good SWR but terrible audio. At first I assumed it was the icom 706 but the kenwood sounds exactly the same. BUT when I do tune on the Kenwood auto tuners it does seem better... at times...
The radioas are between two computers and I also have a echostation interface very close with the serial cable connected to the Icom.. I have tried all combos I can thik of removing and or changing all connection scables etc.. .. do you think even though the antennas tune ok and I know they are not the best (that i could be getting some type of werid resonating? One antenna is a ground mounted vertical the other is a mulit band trapped diploes I kinds suspect both (since they are very old) have bed traps etc BUT I still go back to they seem to tune down in SWR.. help.. it is driving me nuts,, (shirt drive)

thanks any and all ideas are appreciated...

Richard, how many more times do I have to tell you? The impedance looking back into the tuner is NOT the conjugate of the impedance looking into the transmission line towards the antenna - not even when the tuner is adjusted for SWR = 1-to-1.

You lead people astray.

Or did you make the assertion just to irritate yours truly?

Hi Dan,

Tune ONE antenna to lowest SWR;
Change the length of the transmission line;
Does the SWR change?
Yes - you have common mode problems
No - you need a paddle for your canoe

>to another

Sorry, that isn't correct. Maybe the Handbook doesn't emphasize the
point clearly enough, but the design of output networks is specifically
not about impedance "matching".

The objective is to *transform* the impedance of the load at the
amplifier's output socket (usually the design value of 50R) into the
correct value of load impedance needed by the amplifier device.

As Al says, the correct value of load impedance for the amplifying
device is the one that will:

>provide the highest power output consistent with required linearity,
>while staying within the amplifiying device's ratings.
>

The whole point is to understand that the output network is not trying
to match any particular impedance. It's simply giving the amplifying
device the load impedance it needs in order to function correctly.

Those two objectives are not the same... and understanding the
difference is vital for this whole discussion.

Hi Richard,

Thanks for the reply. Sorry, no, I'm not in Connecticut.

I believe the radio that I have is "rated" at 5 watts but
automatically cuts back to 2 watts when used on any of the "dot" MURS
frequencies for which no license is required as long as there is no
interference to licensed stations.

For appearance reasons the ONLY antenna that I can have on the car is
the spring/ball whip. There won't even be an AM band antenna on the
car. CB radios are out for a number of reasons. For one the 108" CB
whip is just as incorrect as the 18" whip. Plus I already have the
MURS radios- a mobile and handheld and my need is only to coordinate
legitimate communications with other existing MURS units at events. I
have a handheld that I can use but a mobile unit would just be easier
and safer to use while moving.

I know that antennas can be "electrically lengthened" with coils, is
there no way to "electrically shorten" them perhaps with some sort of
matching transformer?

Take a look at the MFJ-1798 It covers 80m to 2m. No radials and is only
about 6m tall. Can be ground or roof mounted. I know several owners who are
very happy with it.

Sorry, Hank, I don't believe you can hope for that.

In all innocence, you have rigged the question so that it only allows certain kinds of answers. It has to be a pi network. It has to be "properly" tuned. There have to be reflections.

The question is tied up so tight by its built-in assumptions - the things you believe you already know - that there may not even *be* a correct answer.

Time after time, this same discussion about "reflected power" fails to reach any agreed answer. Time after time, we run the same maze like lab rats... only more predictably... and every time, we fail to reach the goal of a clear, agreed understanding.

And the conclusion of these experiments? That the concept of "reflected power" is not helping us to understand anything.

The irony is that nobody actually *needs* that concept, so you don't ever *need* to enter that maze. Everything about standing waves on transmission lines can be understood much more clearly by thinking only about forward and reflected voltage/current waves.

Dan,
I think you have several options, since a 70 by
130 foot lot isn't all that 'limited'. Trees, 20 to
25 feet tall, make for very nice antenna supports if
they aren't too close together, and if you have or can
have additional supports near the corners of your lot,
you even have room for a 160 meter antenna.
Vertical antennas do work, but the "Whiz - Bang", all
band verticals are more 'whiz' than 'bang', in my limited
experience, and not so limited opinion. A healthy dose
of 'salts' is always indicated with antenna claims!
How things are situated on your property is going to
have more impact on what antenna(s) you can use than any
thing else. If things are not exactly in the wrong places,
almost anything will work...

Dan,
If what you describe as a 'warbling' audio is what I
think it is, it isn't the antenna that's a problem, but
the power supply. Sounds like you're running the power
supply beyond it's capabilities. Drawing too much
current, the voltage 'sags', and causes a 'warbling'
audio, no matter which radio you use (unless both radios
have exactly the same 'problem', which is unlikely). I
guess it's possible, but antennas have very little affect
on transmitter audio.
'Doc

Bruno,
To keep appearances 'correct', how about using a
'hidden' antenna of some sort? You can still have a
'dummy' antenna on the rear fender.
How you 'hide' the antenna depends on what you have
to work with and your ingenuity/imagination, and how
much 'compromise' in appearance you're willing to put
up with. If you think a fibreglass whip instead of a
steel one would look okay, it would be fairly simple.
Just snip the internal wire to the right length. Well,
maybe not so 'simple', but still possible.
Or, how about using very small conductors and glueing
the antenna to a window (burgler alarm tape?)?
'Doc

PS - Put a 2 meter antenna on a '51 Ford p/u like that,
it worked 'okay'...

Dan,

Your space is not all that limited -- most hams find themselves in the same circumstances. I think it really depends on what you want to do.

If you're a DXer and want to work distant stations, multi-band verticals to work quite well. I use a HyGain AV640 (6 bands from 40 - 6, no traps, no radials, full power, individual adjustments on all bands) and it does well with distant stuff but is lousy for local QSOs on 40.

If you are more interested in local stuff, you have enough property for dipoles or loops from 80 on up... and even 160m with a little creative design. I use horizontal delta loops on 40m and 30m, and dipoles on 160 an 80.

You could always put up an all-band "wonder" vertical. But then
augment it with the longest dipole you can stretch betwee your trees,
and feed it w/ladderline plus a tuner. That would kinda give you the
best of both worlds -- one or the other might be better, depending on
band or propagation.

> reflecting reflected power.

However, the 15th edition of the ARRL Antenna Book goes into great
detail about how a match point reflects rearward-traveling waves.
If you are designing RF Power Amps, you can simulate load conditions
with lumped components. If you are trying to figure out what happens
on a transmission line (distributed network) you need to take
reflections into account.

> Transmission lines have reflections; output matching networks and

> by reflections, assuming mismatch.

Impedances created by standing waves are merely V/I ratios, i.e. virtual
impedances. They are the result of standing waves and not the cause of
anything. Physical impedance discontinuities are the cause of reflections
that cause standing waves.

==========

I've been saying for years, the so-called SWR-meter is itself the root of the trouble - it has forward and reflected power scales on it. So it is impossible to refer to it without becoming emotionally involved with the highly misleading reflected power notion.

Furthermore, the confounded thing doesn't even measure SWR. How can it measure SWR on a transmission line which does not exist?

It is a ridiculous, meaningless situation. People drag themseves off to UHF to air their knowledge about such things as echos, S-parameters, circulators and high power TV transmitters. Quite irrelevant to the notion of reflected power at 1.8 MHz.

All that's necessary is to erase the meter scales, or at least wash them from our minds, and change the name of the SWR meter to the TLI. (Transmitter Loading Indicator). Or some other more appropriate name.

Unfortunately, a too-long vertical tends to send the radiation
up at a high angle. EZNEC sez a 6' vertical used on 151 MHz
will have a take-off-angle of about 38 degrees - not good for
vhf mobile.

RS makes a fiberglass CB whip. How about cutting one of those
to your desired length and drilling through the center conductor
at the proper 1/4WL point? Epoxy the hole? Paint the fiberglass
to make it look like metal?

Why not use a dummy load and get the antenna and interface cables out of the equation?
If the problem persists, may be a power supply problem -- filtering or inadequate current handling.
Check the DX power supply with an Oscilloscope - Turn down the power and test again.

It depends on which end of the line you have installed it.

Or are you hedging your bets by locating it at the half-way point?

But wherever it is, it does not measure SWR.

Just because you may think it does, does not make it so!

But it's good to see you didn't disagree with me about TLI's

Yep.
For MW and HF applications:
Wind a half-dozen or so turns of small guage wire around the radio.
Since the orientation of most internal antennas are such that the
ferrite rod lies "east-west" along the long dimension of the case,
winding from the back - over the top - and down across the front
ought to line up your coil properly with the interal antenna
coil and "do it" for you.

One end, then, is connected to a 'long run' of wire out to a tree or
the such. For best results, the other end should be run to ground.

If this radio is mains powered, and there is _any_ chance that the
internal chassis, or metal brackets, or knob shafts, u.s.w., are
exposed, -- *DO NO DO THIS* -- unless you are very experienced and
know what you're doing, and/or have someone that _is_ very experienced
work with you on it.

Hi Dan,

When the SWR changes, this is evidence of common mode currents on the outside of the braid of the coax going to the antenna.

This is a problem because it indicates power is returning to your transmitter and mixing with other functions (poor shielding). The garble you describe "could" be due to this, and the test of lengthening the coax lead to see if SWR changes would verify common modality. It is a very simple test with a very simple result: the SWR changes or it doesn't (it shouldn't in a well designed system).

Hi OM,

Not if it is a high, high, high frequency device like a wireless
phone.

Not if it is a high, high frequency device like an FM walkman (well
maybe).

Sure, if it is a short wave or AM radio.

Wow. Maybe I need to issue a "challenge".

How about this: If you can't prove that F does not equal m*a, then I am right about whatever issue on which we disagree!

Is that how it works, Cecil? ;-)

Richard Fry wrote:
"This topic deserves more attention---."

Then Richard Fry attached a paper which includes:
"If the source impedance were equal to the fifty 0hm line impedance, half the transmitter`s output power would be dissipated in its internal output source impedance."

For a specific transmitter, that is certainly possible, but the statement is wrong as a general statement.

Many transmitters, such as the familiar type that uses a Class-C final amplifier, are 60 to 80% efficient..This does not mean it is not adjusted for maximum power transfer. It may well be conjugately matched and still exhibit high efficiency, the reason for using the Class-C configuration.

The internal resistace of a Class-C amplifier consists of two parts. One part gets hot and the other does not.

The part that gets hot is ortdinary loss. The part that does not get hot is the switched-off time of the final amplifier. It is just as adept at opposing transmitter output as is the common resistor, but it makes no heat.

Best regards, Richard Harrison, KB5WZI

YOW!

Raise the sucker as high as you can, and extend the data wires to the point of use.

OR

Raise the sucker as high as you can, build a reflector or dish around it; and extend the data wires to the point of use.

Beyond that, you stand to lose more than you gain.

> Just so I can get my thinking straight -- Does a slotted line measure
> VSWR?
==========

No! A slotted line cannot measure VSWR.

But the VSWR on a slotted line can be measured. That is what it is there for. The slot allows access by a probe to the inner conductor.

It does not allow or facillitate the measurement of VSWR on any line other than on itself.

It is primarily used to make impedance measurements of R+jX etc in a standards laboratory. The Ohmic Standard is the characteristic impedance, Zo, of its own internal transmission line. Very accurate and stable.

That depends on what bands you want to work, time of day you operate
and whether you're after DX or closer-in stuff (such as closer than
1500-1000 miles). Well-installed verticals are fine for DX but if you
want to ragchew on 80 or 40 they're not the best choice.

Also be aware that most manufactured verticals are severely restricted
in "SWR bandwidth" on 80 and to a lesser extent 40 meters.

> I

> suggestions.. what am I missing ? verytical or diploe type or
> somethign else.. Thanks for any suggestions

With a 70 x 130 foot lot you have room for a full-size 80 meter dipole
if the trees and house are in the right spots. 40 meters can be
handled by a second dipole in parallel at the feedpoint, or with
easily-made traps.

If your house is in the middle of the property and there are trees at
the edges or ends, consider putting some TV mast on your roof, vent
pipe or chimney, and supporting the center of the dipole. The trees
support the ends. If your house is 2 stories and you use 15 feet of TV
mast the center will be at least 35-40 feet up and the ends 20 feet or
so.

Source record: 94278

With a skip condition I am able to pick up BPL signals from a distance.
The rotator shows it is coming from the east coast...
Is there any way I can tap in on these strong signals to get free
internet. The frequencies I can pick up go from about 18 to 35 mhz with
my particular antennas. The other day there were two sources of the
signal coming from farther north, possibly somewhere in Mass... If
these companies are going to put signals on unbalances long wires for us
to pick up and possibly interfere with our ham communications, there
must be some kind of I.D. so we can report this interference... By the
way I worked Don Stoner, W6tns 40 years ago. I was in Japan at KA2YA and
he was in California..running 200 mw to a transistorized rig.. 1st of
it's kind... Very low power goes a very long way.. If you would like
information on BPL I can copy during skip conditions I will be happy to
coordinate and experiment on these signals... With 30 or so sources,
when the skip is in, you can count on destroying HF communications and
Shortwave broadcast... possibly world-wide...

Have fun till the RF hits the blower... Say hi to Michael for me..
When he retires I know who he is going to work for...

Walter McKay w5sfp.

Oh yes! The local cable company was fined for leaking signals from their
coax cable... Their signal levels were 1/200 as potent as the presently
measured local BPL...

Did you hear the one about the water temperature transmitter off the
coast of South America that was interfering with the U.S. government
communication and also marine radio traffic... 100 mw. check it out.

Bye... and have fun with your power line adaptor.

That's how your logic obviously works, Jim. Most of us know
that it is impossible to prove a negative except for a binary
outcome.

Please, pretty please with cream and sugar on it, provide just
one single example of a standing wave without forward-traveling
or rearward-traveling components. That is certainly not too
much to ask.

3127. RF absorption question 40m

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-29 00:42:35 UTC
From: Antenna Problem <orillia@rogers.com>
Message-ID: <%%Qtc.2814$JmE.2803@news04.bloor.is.net.cable.rogers.com>
Source record: 94282

Just put up an end fed 1/2 vertical cut for 40m. I was able to get a low SWR with my antenna tuner. The problem i found was the wire got tangled into the lower branches of the tree. My plan was to pull it away from the tree however the wire follows straight beside the trees. Will i have an RF absorption problem on 40m? Should i get the tree guy in to trim the branches so i can pull it away from the tree? Or should i just drink a few cold ones and enjoy this holiday weekend?

Source record: 94287

Rich:

Well, as 2m transmit is 144-148, the antenna will be too short for the 2m band, and the spacing of the 4 bays will be too close.

Generally speaking, it's usually easier to cut down element length on a lower frequency antenna to bring it up to a higher frequency. Depending upon the design, this may not result in a reasonable gain figure for an individual antenna...

I'm assuming that when you say 4-bay, you mean an antenna array with 4 separate antennas in a 2x2 (square) configuration, which for the original design frequency range, would have yielded nearly 6db of gain over a single antenna of the array.

If you are serious about making the array work on 2m, the first thing you will need to do is to increase element lengths to bring resonance of the individual antennas within the 2m range. This may not result in near the gain the original antenna had at it's design frequency because the spacing of the elements will no longer be optimal. You might be able to model it in NEC, ezNEC or one of the other antenna programs to see what the current antenna gain and bandwidth figures are, and then change lengths of the elements (leaving the spacing the same) and see what the new antenna looks like.... Of course, even if it's ok, then you have to figure out how to "stretch" the elements to fit. Once you figure all of this out, and get a single antenna with decent gain at your frequency of interest, then you need to repeat it three more times, then connect them at the optimum spacing with an appropriate phasing harness for 2m operation....

If you haven't guessed by now, it may be easier to just sit down and make (or buy) an antenna with about the same gain figure the existing 4-bay has, and save yourself a lot of time. However, if you're willing to spend a bunch of time piddling around and aren't looking for optimum results, it can be a lot of fun to modify something like what you have, if you enjoy cut and try and have a lot of time on your hands...

Good Luck

>Richard Clark, KB7QHC

Actually, there is no problem.

As it stands, at the impedance looking into the coax (TX end) won't be
50 ohms. To keep the TX happy, all you need to do is to insert a simple

matching circuit (at the TX end) to transform whatever the impedance is to 50 ohms.

This won't change the impedance looking into the coax, and the SWR on the coax will be the same. As a result, the loss on the coax will be higher than if the SWR was 1:1. However, as the length of the coax won't be that great (even in those large American cars!), I doubt if you'll notice it.

For a suitable matcher, I suggest you get one of those very cheap small CB type (the kind in with the two compression trimmers, often found in a junk box), and rebuild it into a C-L-C pi configuration (if it isn't already). The coil will probably be about 4 turns 1/4" dia (some experimentation will be necessary). To adjust the matcher, insert an SWR meter between the TX and the matcher, and connect the matcher to the coax.

Cheers,
Ian.

Technically correct, but far too late. "SWR" is everywhere - the genie
is out of the bottle, and it won't go back.

To expand on what Reg already knows, but clear needs to be said again
and again...

The only way forward is for everybody to understand that SWR numbers are
just one of several alternatives for judging the "goodness" of an
impedance match to some specified reference impedance. Other
alternatives include reflection coefficient, return loss, gamma, S11,
etc.

All these alternatives are equally valid, and any one can easily be
converted to any other by doing a small amount of math. RF engineers do
it all the time, and it's absolutely no big deal.

If you're only using "SWR" as a number that indicates the goodness of an
impedance match, you can legitimately apply it to *anything* that
possesses an impedance (it doesn't need to have waves standing on it).

The discussion goes off the rails when someone starts to imagine that an "SWR meter" is truly *measuring* standing wave ratio. It isn't - it is actually measuring one of those other quantities (magnitude of reflection coefficient). Then there has to be a mathematical conversion from that number into the more familiar SWR number, which is done by calibrating the meter scale in a specific non-linear way.

It's vital to understand that difference: the instrument is *calibrated* in SWR, but it is actually *measuring* something else.

Likewise it's a mistake to believe that a Bird Thruline wattmeter is measuring "forward and reflected watts". It is just another gadget for measuring reflection coefficient, with a fixed sensitivity that allows the meter scale to be calibrated in watts. But it's only a calibration in terms of power - the Bird is not making a power measurement.

When my son was into hi end (actually hi noise) car stereo of something called Outlaw SPL, I ran across an ad in one of the magazines devoted to the "sport" which pushed a "no loss" fuse that would allow better current stability for that 2 KW amp in the trunk. $35 each.

The ONLY thing an SWR meter measures is the "Magnitude of the reflection coefficient relative to an arbitrary value of Ro", where Ro is usually 50 ohms. It actually throws away the other half of the possible information, ie., the "Reflection Coefficient Angle".

99.9 percent of radio amateurs have never heard of such a quantity. There's no reason why they should. It's of no practical use or interest.

But they are VERY interested in whether or not their transmitter is correctly loaded with 50+j0 ohms during transmissions and a simple indicating instrument is essential.

Isn't it time some enterprising manufacturer came into the market?

We are assuming you have a 4 bay dipole array, common for commercial use. Some of these are basic dipoles fed with a gamma match and it would be fairly easy to lengthen the elements and retune the gamma match. Other brands use a closed loop dipole and that would be a challenge to cut and lengthen. The phasing harness would be a specific length for 160mHz center freq and you may need to make a new one for optimum results on 2m. If the harness if too long or too short it may tend to pull the pattern up or down slightly from the horizon.

Hi group... Need some input.

I need to stack two 432mhz quads, not in the traditional vertical plane, but horizontal. This brings me to two questions... (1) What distance apart? 1/2 wave length or 1 wave length or ?? (2) Do I need to make that measurement from boom center line to boom center line OR would it be end of element to end of element?

Thanks & 73,

Steve

I'd start with putting it on a (low power) radio and meter and seeing what
SWR you come out with in the portion of the 2m band you intend to use it on.
If it's less than 2:1 most would consider that acceptable. (Personally, I'd
shoot for less, but that's me). Depending on how 'wide band' this thing is,
it might cover 2m nicely.

If you want to actually alter it for 2m, it will involve:
Lengthening the antenna elements (2m is lower, so elements are longer)
Lengthening the phasing elements
Increasing the spacing between antenna elements.

assuming they are being fed in phase and are polarized the same way they should work best at an odd multiple of 1/2 wave apart... measured boom to boom. of course at 70cm a 1/2 wave spacing is only 35cm, which is pretty close and will probably result in unwanted interaction between them. i would go for at least 3/2 or 5/2 wave spacing... 3/2 spacing is only about 1m which is very workable even in a small space and would be reasonable for fairly short quads. if they are long ones you may want to go for 5/2 or even wider spacing. one kind of generic rule of thumb is that you want them at least as far apart as their boom length..

one other thing, this is not an odd application. it is fairly common to see horizontal stacking of yagis for vhf and uhf. cushcraft used to sell a pair of 2m yagis with a cross member and phasing line. many big gun uhf stations will stack 4x70cm yagis in a square with an H shaped framework.

==========

Jean, look no further.

I assume your 'restriction' is the amount of space available, and the consequential environmental clutter which doesn't help.

From the important point of view of power radiating efficiency the magloop is the most efficient of all the small antennas. Much more efficient than most.

Small means small in relation to free-space wavelength. A loop diameter less than about 1/8 of a wavelength can be considered to be small. But loop antennas with a diameter as small as 1/80 wavelengths are quite usable when installed in a fairly clear and unobstructed environment. But don't let the prospect of using one in your bedroom or attic put you off.

With a wide range tuning capacitor a magloop can cover several bands, eg., 160 to 40 metres, or 20 to 10 metres, whereas other very small antennas are single band only.

Assuming you are not going to buy one.

A magloop consists of a square or hexagonal or circular loop of a LARGE diameter (one or two inches or more) conductor. Or a broad, flat strip. The actual shape of conductor doesn't matter all that much. A circular conductor is marginally the best. What matters is the enclosed area. Copper is marginally better than aluminium.

Construction of the loop itself is a straightforward mechanical task. The main difficulties lie in connecting the ends of the loop to the tuning capacitor. All connections MUST be of the same substantial construction as the loop itself.

The variable tuning capacitor, a vital component, for the highest frequencies (14 to 30 MHz), can be self-constructed. For the lowest frequencies variable capacitors (the vacuum type) as large as 1000 pF are

needed, and these can only be purchased. They are expensive but worth the money. They have a resale value.

For single band working a high-value fixed capacitor can be be used with a low-value home-made or purchased variable capacitor in parallel.

All capacitors must have high working voltages. For 100-watt transmitters working voltages of 5000V are needed. The smaller the loop diameter, the lower the frequency, the higher the working voltage.

The only other component is a small internal coupling loop which lies in the same plane as the the main loop and, to match to a 50-ohm line, it has a diameter about 1/5 of the main loop. It is a valuable property of a magloop that the diameter of the coupling loop remains approximately constant from one band to another, the only variable quantity needed to maintain a match to a 50-ohm line is the value of the tuning capacitor. (All other antenna matching circuits need at least two variable components.)

The coupling loop can be just a self-supporting circle of wire of no greater wire diameter than that of the inner conductor of the coaxial cable which feeds it. Ignore old wives' tales about Faraday screens. But if you feel like it, by all means extend the coaxial braid and jacket around the length of the coupling loop.

Especially at the lower frequencies, a very slow-motion control is needed for the variable tuning capacitor. This is necessary because of the extremely high Q and selectivity of the loop + capacitor tuned circuit. You can't have high efficiency without a high Q with magloops.

Well, I've given you the essentials. You will find on Google the various ways of making your own tuning capacitors complete with drawings - the most awkward part of the whole business. The first thing to do is obtain the values of the variable capacitors. See computer program below. Being lazy and rich enough I've always purchased mine.

To design your own magloop, or, once you have the dimensions, to compare the performance of one manufactured magloop with another, download in a few seconds program MAGLOOP4 from website below and run immediately. Program MAGLOOP4 has been written to professional standards.

3150. Radials for 6-BTV

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-29 21:43:47 UTC

Message-ID: <3muhb051u7kocjd0566gv8cj1au0oc5dbp@4ax.com>
Source record: 94305

In an above ground installation, Hustler recommends a minimum of 2 radials for each band. That's 12 wires, the equivalent of 6 dipoles.

Now, I'm wondering, why bother with the vertical section at all. If I put a PVC pole up 25' (the height of the 6-BTV) and tie all the radial pairs as inverted vees to one feed line at the top, wouldn't that work as good. What effect would the feed line have on the radiation pattern?

The dipoles would also serve as guy lines.

Maybe a balun on the top?

I have had inverted vees in the past and they seem to work great.

Here is a chart of what the EME'rs are doing for spacing on 2m. Scale
by exactly 3 for 432 for your boomlength.

http://www.vhfdx.net/VE7BQH.html

And here is the DL6WU stacking formula -

DL6WU Stacking Formula for Long Yagis

D = W / (2 * sin(B/2))

* D = stacking distance, vertical or horizontal
* W = wavelength, in same units as D
* B = beamwidth between -3dB points.
Use vertical beamwidth for vertical stacking (as above);
use horizontal beamwidth for horizontal stacking.

Or you can do it using YO, EZNEC, etc., and increase the spacing until
the first sidelobe is minimized, and the next stacking distance step
makes it larger. I think that's at 13dB down, but I could be wrong,
17dB also sounds correct. ;)

How big are the antennas? The pattern can get pretty sharp and hard to nail on the station you're trying to peak. No doubt you'll be loud once you're there, but the wind may blow you off track.

Another one of the all depends questions. If you want a clean patern it is
one spacing, maximum gain is another.
Forget stacking quads at 432 and go with a longer length yagi if you want
the maximum gain.
Quads are good for maybe 6 meers and lower. By the time you get to 2 meters
it is beter to go with a long yagi as the aditional gain of quads start to
fall off compaired to yagies of the same boom length.

You're forgetting the take off angles. On 40 and 80 meters you'll
have a cloud warmer. Also, I'd think the odd-multiple relationships
(i.e. 40 meter radials working as a 3/4 wave on 15 meters)
could be exploited...

Pete

I verified that just about 13 dB down on the first sidelobe gives you
the best pattern, and is about .2 down from highest gain.

Ron,

An inverted V has a different radiation pattern than a vertical. Plus, the multiple dipoles will interact with each other regarding adjustment.

I could discuss it further but since your email address is not valid, I didn't want to spend the bandwidth here, hi. I guess deleting the "dot" might get the right address but I'm a little pressed for time to play guessing games right now, hi.

73s,

Evan

I am fairly local to you, Manchester way. I have a pile of assorted
Aluminium tube. I have to scrap, some time within the next 3 weeks. Old CB
ants ground plane rods and the like. Your welcome to it, the council are
compulsory purchasing the land my storage unit is on, so I have to empty it.
There is a 3 ell 6 meter beam, and all sorts of bits.
A Cushcraft butterfly mini beam, all damaged but the bits may be useable,
most of its just filthy, and will clean up.
Any how your welcome, if you can be bothered
to collect. It's better than the tip pikies getting it!
But,, if you want to pay, Knights CB have tons of spare bits for
sale.

3167. Stacking Distance Question. More Information

Thanks to Tom, Dave and the rest of you that answered my question so quickly.

I thought I should give a little more pertinent info on this project. A elderly ham friend of mine is putting together a 70cm fast scan TV station. He chose the quad because of its wide band characteristics. His tower is Rohn 45 at 73 feet. It has a Glen Martin "Voyager" trolley/tram system. The steel mast is above the bearing plate about 14 feet. Out the top of the steel mast is 6 feet of thick wall fiberglass tubing. The two 70cm quads will be on a fiberglass cantilever arm that is approximately 48" long. It slips over the fiberglass mast and bolts into place. (arm required to clear the tower when cranking antenna system down) This arm will have two, 1 1/4" diameter post sticking up vertically to mount the quads. Here is where the question arose about how far apart the quads should be.

I don't think I could/should push the cantilever arm out any further. The system, all together, could probably withstand a little longer arm if required. ?? Three 1/2 wavelengths would be ~39 inches.

The quads are 7 1/2 feet long with 12 elements each and weigh 3.5 pounds.

We have no modeling software, just a desire to do it right the first time.

Thanks again & 73,

Steve

sounds like a lot of joints that could slip. i wouldn't expect a lashup
like that to survive very long up here in ice and wind country. i would
get rid of the '1 1/4" posts sticking up' and mount the quads right to the
cross arm. and unless that extra 6' really is necessary i would mount the
crossarm directly to the steel mast. which way are these going to be
polarized, horizontal or vertical?? even if vertically polarized they
should be ok being 2' out from the steel mast i would think.

3169. Confirm the resonant frequency of this folded dipole

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-30 13:16:49 UTC
From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <2hu55hFfsdtoU1@uni-berlin.de>
Source record: 94173

Hi. Can anyone please confirm for me the resonant frequency of the folded dipole below?

(I calculate abt. 159.025 Mhz).

```
L1
-----------------------------------
| | L2
--------------x L4 x---------------
L3 L5
```

Tube diameter = 10mm

L1: 90Cm; 35.43"; 2.953'
L2: 70mm; 2.76"; 0.230'
L4: 5.8Cm; 2.28"; 0.190'
L3&L5: 42.1Cm; 16.57"; 1.381'

L4 is fixed at 58mm, that is the distance between the bolts where the dipole attaches at the feedpoint. I guess I'm ignoring the connections within the plastic connection box, that would perhaps add 2.54Cm; 1.00" ; 0.083' to L3 and L5, which I suppose might make L3 & L5 44.63Cm; 17.75"; 1.46'. But is that of any real significance with such a wide-band antenna. Probably not eh.

BTW, Anyone know of an online calculator specifically written for VHF, tube-made, folded dipoles? TIA. Rich.

P.S. I'm seeking the dipole to be resonant at 159.025 Mhz.

Evan,

If I thought I would be getting Email response to this post, I would
have included a good address, sorry.

I have decided that I will do a little experimentation. I have a
tripod on the back dormer with a 2m ground plane that is only 5 feet
above the roof. I can use that for an easy access connection point and
run a few dipoles sloping down from there. I will start with 40, 30
and 15 and see what happens. If that works, I will add more bands.
Once I have the lengths worked out, I can raise the center point.

I would be interested in any idea you have on the subject.

Just realised might mean for HF antennas ... I am referring to VHF/UHF
use only. The dipole centres and element to boom fittings are of the
TV and FM antenna variety and not suitable for HF beams.

As to calculators,I found two, but they are confusing to me.

Not very clear to me how to use this one:

http://n-lemma.com/calcs/dipole/fdipole.htm

Or this one:

http://www.optcom.net.au/wireless/folded_dipole.html

No, if we all made one, they would all have slightly different
resonant frequencies. If you want one that is right on frequency,
you have to trim it to that frequency and then don't change
anything about it or its environment.

I am finally going to put up a VHF antenna for 2 meter and another antenna
for 70 cm.

What is type of coax should I use? Rg213? Or will RG213 be too lossy?

Recommendations please...

Rob

Richard

Thanks for the references to the folded dipole calculator sites. If you
dont have the calculators figured out, you are welcome to E-mail me. They
seem OK to me.
I've been building some dipoles for 137MHz and have 'grid dipped' some
lengths for dipoles that indicate that your dimensions are very close to
correct.
Do you have any doubt that the antenna you describe will radiate well at

159 MHz?

Jerry

If the elements are of different diameters, example 0.5 inches and 0.375 inches there are differences in Zo and slight differences in Fo.

To a first approximation I calculate 158.5 MHz as resonant point. That may have a 2 to 3 percent error due to endeffects, L/D ratio etc.

Your calculation is a good as mine.

DD, W1MCE

A well designed yagi would have had plenty of bandwidth, but that's moot
now, I guess.

I would say 1.17m H plane, or 1.06m E plane would be pretty close.
That's based on an estimate of your gain. You could email me the plans,
and I would find where the 3dB points really are.

Are you deluding yourself about the degree of accuracy required?

An error of 1 MHz in 159 MHz would make no detectable difference in behaviour or performance.

Hi Cecil,

I went to the url k4wge indicated for Steve's work and found that he has a book on antennas published by Noble Publications going for $207 after a 25% discount. I would need to know the quality of editorial review it survived before spending that much on a new book. I'm wondering if the book had ANY technical review before printing.

I'm also wondering how much of the stuff from his three-part QEX article will appear in his book. That article is chuck full of erroneous material. I know you and others on this thread tried to correct some of his incorrect notions to no avail. And you know that he and I went at it pretty strong, but he wouldn't listen. He told me early on that my concepts of matching appearing in Reflections are wrong, and said that using the statements I made there he could prove me technically incompetent.

In two Communications Quarterly issues he said as much, referring to my writings in Reflections and in QEX.. During our last email communication he reiterated his comment concerning incompetence, and said he was going to write a definitive article concerning matching that would prove it, but that this time he wasn't going to mention me by name. That 'definitive' article is the three-parter in QEX.. Well, he didn't mention me by name, but he presented one of my examples, number for number, and then erroneously tore it to pieces. Anyone having read my work would recognize that he was targeting me even though not by name.

Enough of that. I've been reading a little mail on the rraa, and I see you're still hangin' in there. Hope you're well, but I guess you must be, cuz you still have that characteristic sarcastic (no that's not quite the word for it) response at the right moment.

Take care,

Walt

Cecil,
I don't think they sell the water pipe any more. I have the CPX stuff on
432, 9913 for 6m inside, and LMR400 if somebody else is paying for it.

3194. MFJ Tuner

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-30 20:50:07 UTC
From: dan_hoffard@hailmail.net
Message-ID: <648fff84.0405301250.6ee75ece@posting.google.com>
Source record: 94198

Is anyone familiar at all with MFJ tuners? Mine is a 941B.. It has a little red button just above the RF/SWR meter.. Do I need to push this in to get the SWR reading? When I hold it down and play with the knobs I am able to get good SWR, but if I don't hold it down, the SWR never gets below 3. There is also another dial that says SWR/WATT that can be pushed in or pulled out.. The online version of the manual talks about pulling and pusing this dial but never mentions the little red button.

I tried hooking another SWR meter up between the xcvr and tuner and the reading is similar to what I see on the tuner when I press the red button but not exactly the same.

Thanks,

Dan H.

Walt, as you know, I tangled with Steve over the subject of interference which he claimed didn't exist at a match point. He later changed his mind and told me in an email that he needed to rewrite part 3 of his article. Maybe he got it right on his CDs. _Optics_, by Hecht proves Steve's equations in part 3 to be the actual interference equations from optics with RF Power substituted for light Irradiance.

IMO, you and Steve were much closer in principles than either one of you realized.

He said in Part 3: "... the two rearward traveling waves at the match point (rearward waves 1 and 2) are 180 degrees out of phase with respect to each other and a complete cancellation of both waves occurs."

You said in Reflections II: "With equal magnitudes and opposite phase at the same point (Point A, the matching point), the sum of the two (rearward-traveling) waves is zero."

This agrees with J. C. Slater, from _Microwave_Transmissions_, "The fundamental principle behind the elimination of reflections is then to have each reflected wave canceled by another wave of equal amplitude and opposite phase."

All three above appear to me to be in agreement so the disagreements are really about the down-in-the-noise details. Some gurus on this newsgroup disagree with you, Dr. Best, and J. C. Slater.

Others on this newsgroup have been asking about your opinion of conjugately-matched transmitters. I have no interest in that particular discussion but you might point out some references.

Howdy,

I'm moving into a house where I can't put up an exposed HF antenna. Any comments on in-attic antennas? I'm bringing my 10-15-20-40 meter shortened dipole with me. I think it will stretch out ok in the attic.

Thanks,

Jeff

I run 25W into a dipole in my attic for 10M; when the prpagation was in, I was able to work into all of Europe, and out west as far as Central Kiribati and New Zealand. An attic dipole will work..just not as well as a 20-element Yagi at 150'!!

Source record: 94204

I just took the anual 8-hour HAZWOPER (First responder at operations level) HAZMAT course; one of the areas covered by our instruction was on protective equipment. He told us of an incident in Lynn, MA; the FD responded to a fire at a chemical company. The fire was in an area where there was a 100-pound vat of molten sodium. One of the firefighters threw a shovel ful of sand on the sodium.
In solid form, sodium is highly reactive. In molten form, if it comes in contact with ANY water, it explodes.
Maybe there had been some water on the shovel..or maybe in the sand.
Either way, the vat exploded.
There were seven firefighters in the room. All seven had disregarded instructions, and had their turnout gear in various forms of disarray.
All seven suffered severe, third-degree burns where their turnout gear wsasn't as it should be. All seven are now permanently disabled.
1) ALWAYS use protective gear properly.
2) Never, NEVER mess with elemental sodium!!!

Hi Jeff (et al.),

Of course, it won't work as well as a full-size
antenna outside in the clear. But, it should work
just fine. I worked my first 140 countries or so
with attic dipoles and a barefoot transceiver.
So, it is certainly possible to work lots of DX,
as well as other stuff, with an attic antenna.

73,
Bob

>When all else fails read the manual

Hi Dan, Good advice, but he has already read the on line manual, if you read the post. The 941E must be a later version of the 941B, which he is asking about. The only thing I can figure is; the 941E has a dual (cross hair) swr/ power meter. If the B version does not (and I don't know) the button in question may be a forward/reverse switch, which would explain why he only gets good readings when he pushes the button.

>IMO, you and Steve were much closer in principles than either one of you
>realized.

Sorry Cecil, I don't think so. Steve has missed the most vital aspect of the phenomenon--what happens to the energy, or power in the reflected waves on return to the match point.

>He said in Part 3: "... the two rearward traveling waves at the match point
>(rearward waves 1 and 2) are 180 degrees out of phase with respect to each
>other and a complete cancellation of both waves occurs."

Yes, but Cecil, the cancellation of the waves is only in the rearward direction, because at the match point the waves and the energy they carry (volts x amps) are totally reversed. Now to continue what Steve said is: "The result of this wave cancellation is that the total steady-state rearward-traveling wave has a net voltage of 0 V nd 0 A, respectively, and an impedance match occurs." No No No.

As we've discussed earlier, voltage and current cannot both go to zero simultaneously, except in the rearward direction. When voltage goes to zero at the match point because the two returning voltages are equal magnitude and of opposite phase, the current is doubled and the V x I energy in the rearward traveling waves is totally re-reflected in the forward direction. Steve totally ignores the energy in the reflected waves, except to say, "A total re-reflection of the reflected voltage, current and power does not occur at the match point and it (re-reflection) is not necessary for the impedance match to occur." This statement is totally untrue, because as I said above, all of the power in the reflected waves of voltage AND current is totally re-reflected in the forward direction, the same as if the E and H fields had encountered a physical short. We all know what happens in this case. The only difference is

that the virtual short established by the wave interference is one way only--to the rearward traveling waves.

I know you don't agree with me that a one-way virtual short is what causes the re-reflection, but in a short time I'll be able to prove it to you in a manner you'll not be able to rebut. Stay tuned.

>You said in Reflections II: "With equal magnitudes and opposite phase at the
>same point (Point A, the matching point), the sum of the two (rearward-
>traveling) waves is zero."

Which means zero impedance, the boundary condition causing the total re-reflection. This exactly what Slater is implying.

>This agrees with J. C. Slater, from _Microwave_Transmissions_, "The
>fundamental principle behind the elimination of reflections is then to have
>each reflected wave canceled by another wave of equal amplitude and opposite
>phase."

Cecil, the Slater reference is where I originally obtained this concept for my QST article that appeared in Oct 1973, nearly 30 years ago. Check the ref number in Reflections--No. 35.

>All three above appear to me to be in agreement so the disagreements are really
>about the down-in-the-noise details. Some gurus on this newsgroup disagree with
>you, Dr. Best, and J. C. Slater.

Those who disagree with Slater need to refresh their memories with a review of transmission lines 101. They ain't gonna win.
>
>Others on this newsgroup have been asking about your opinion of conjugately-
>matched transmitters. I have no interest in that particular discussion but you
>might point out some references.

Cecil, I don't have a particular reference handy, but I can quote some of my own measurements the others you mention might find of interest.. IMO they'll have a hard time disgreeing with the data if they don't already believe a transmitter is conjugately matched to its load when it's delivering all of its available power at an arbitrarily selected drive level within the normal operating range. Those who don't believe will get quite a surprise when I reveal what the output source resistance of the xmtr really is under this condition. Waddya think?

I have a zig-zag 100' dipole in my 40'X35' attic. I feed it with 450 ohm line and a home brew tuner. I keep a regular schedule on 75M and 40M with hams 350 miles out to 1000 miles with 100 watts. DX 20M on up. Yes, an attic antenna will work, and it will work all of you home electronics, as well as your neighbors, so get ready for that!

When trimming multiple dipoles on one feedline, start with the lowest
frequency one first. It may take more than one iteration. Best if you can
run EZNEC on it first to get in the ballpark. My gut feeling is to not put
the wires for adjacent bands next to each other.

3208. Thoughts on odd behaviour of 10m vertical

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-31 01:30:21 UTC
From: Arfa Daily <monitech@freeuk.com>
Message-ID: <Xns94FAFF716E35arfadailyitsalljustb@62.253.162.203>
Source record: 94211

Hi all

I have an odd situation with a Solarcon Ground Zero antenna operating on 10m. I am short of space, and dont have room to erect a traditional silver rod type vertical, or anything with a large radial system, so I cast around for something that would fit the bill and go on my existing mast. I came up with this Solarcon antenna. It is a continuously loaded - ie helically wound - monopole, about 4 feet long. It claims to be a groundplane-less electrical half wave, with voltage feed at the base, via what they call their patented " sidekicker unit ", which appears to be some kind of clamp mounted ferrite balun. It is able to be moved up and down a small section of the antenna to facilitate VSWR adjustment. It claims to be ok for use on fibreglass truck cabs etc, and does not require a conducting mount. I only wanted it for fairly short range local FM chit chat at 29Megs, and access to my local 10m repeater about 6 miles away. So far, so good.

Initial trials were carried out indoors, with the antenna fixed in a chemistry clampstand, about a foot above a bench, and fed with about 10 feet of coax. The VSWR set up PERFECTLY at 29.5MHz, and a < 2:1 VSWR was maintained over a couple hundred kHz. The repeater could be accessed with only a few watts, and a good signal was received from it.

I then mounted the antenna at the end of a 4 foot 1.5 inch diameter duralumin pole, and clamped this to my main 2.5 inch diameter station mast, at a height of about 4 feet above ground, and ran the full final length of coax back to the transmitter. I then carried out some final VSWR tweaks and repeated the tests with the repeater. Again, results were good. I also ran some simplex tests with a friend located near the repeater receive site, and again, results were good.

I then moved the antenna up the mast to what I hoped would be its final installation position at around 15 feet above ground - and here's where it all went wrong. A recheck of the VSWR at this point revealed that it had not changed, so the antenna was not being detuned in any way. However, the performance was now absolute crap. I needed over 20 watts to access the repeater, and the returned signal was 5 S points down. My friend could no longer pull me out of the noise below 5 watts. Several hours of tests then followed, and the upshot of these was that the lower I brought the antenna, the better it worked.

I am now at a total loss to explain this. As an electrical half wave, the antenna should not require a ground system to work against, and this would seem to be the case, as it tunes up so well. I thought maybe the radiation angle was rather high, although again, it shouldn't be for a half wave. If it were, maybe the ground was having an effect on this, and

pulling the radiation angle down. I'm loathe to believe this though, as the antenna is originally designed as a groundplane-less type for CB use, and this is primarily a short range band requiring a good ground wave.

Does anyone have any thoughts on what is going on here, and whether anything can be done to improve the situation? I have also considered using a Boomerang instead, as this can be centre mounted and is designed to work stood off from a pole similar to my situation.Again, any thoughts ?

I would appreciate any replies direct to

monitech@freeuk.com

One thing to consider is that many (if most) newer homes (apts, ect) have Ground Fault detection devices
installed in the wireing- get ready to find these tripped, as they dont like strong RF fields! (or replace them with conventional outlets, but be aware of the shock hazard)! Have friend , on 6 meters with a 2 el quad in a dormer in an apartment gets out rather well during band openings, and it rotates!, but doubt practical on 10, or below! If you have METAL (not plastic!) gutters, might be possible to load them with an antenna tunner, or place wire in plastic ones, perhaps working a counterpoise as a surface wire on the ground. (again with an antenna tunner. Good luck-- Jim NN7K

3211. Recomended mid-range shortwave set-up

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-31 05:58:35 UTC
From: Steve <abc@123.com>
Message-ID: <fQzuc.76675$gQ6.4150@newssvr25.news.prodigy.com>
Source record: 94228
Cross-posted to: rec.radio.amateur,rec.radio.amateur.antenna,rec.radio.amateur.equipment

Hi,

I have wanted to get involved with shortwave for years and would like to get some recommendations on a mid-range ($200-400) receiver and antenna set-up. I plan on telescoping mast for shortwave, TV (mostly for uhf PBS stuff), and FM. The height restriction in our town is 50' but I imagine anything around 30' would produce good results since there are no big hills or trees nearby. In addition I own a newer 2.8 GHz PC running Windows XP for any recommendations on how I might incorporate this into the overall set-up.

Being inexperienced I am thinking I should start with simply listening with a capable mid-range receiver and then after some years time buy into a transmitter as well. This is all untutored preliminary thinking on my part and would welcome anyone's ideas as to how a beginner could best get started on the road to mid-to-high end shortwave/ham listening/broadcasting. I see this initial step as phase one of a two or three part program that will extend over a period of five or ten years.

Thank you for your help.

Steve

Note: I will be buying "Passport to World Band Radio" as a way of educating myself on some of the issues I mentioned

Have fun - use twin-lead 300-ohm or ladder-line 450ohm...
use a half-wave u-shape balun + a 1/4-wave stub on each end - and your runs
can be pretty long without a lot of loss - or a lot of expense.

I'm afraid this is largely a myth from the Olden Days. Back then, twin-lead was probably better than most types of coax that hams could buy... but coax has improved, and twin-lead hasn't.

The myth has been overly influenced by a few measurements dating back to the 1950s, made under ideal conditions that can't be achieved in real installations.

The reality is that twin-lead is difficult to install, sensitive to electrical disturbances, of very poor quality if it's also low-cost, and *very* sensitive to getting wet. The higher in frequency you go, the more each one of these things matters.

(Yes, I know there are a billion TV sets out there using twin-lead - but that doesn't make it right. Most viewers in the USA have been brainwashed to accept appalling standards of TV picture quality.)

Parallel-line can be excellent for power distribution and phasing *within* a stacked array. I've used it on the moonbounce array at 432MHz, in a wet climate, but those were short, straight lines that are self-supporting with mostly air insulation - a completely different thing.

As many others have said, it depends how important low loss will be for *your* particular application.

If a significant length is involved, and you're interested in weak signals, then RG213 (full quality, no substitutes) should be your minimum specification.

People in the USA can recommend specific brands that will be available
to you.

A REAL radio amateur is NEVER satisfied with the coverage or signal
strength!

However, the lack of signal strength in the elevated location could be
because of multipath reflections, and the antenna is now in a null wrt
the repeater antenna (this can happen on 10m).

Well, maybe.....

Ian.

Geof,
All antennas are affected by 'ground', real (dirt), or the
artificial kind (radials/counterpoise/??), not to mention
everything around it. That's why you 'tune' one, right? I'm
not familiar with the particular antenna you speak of, but I
see no reason why it should be different.

Jeff,
Since you have already used an 'attic' antenna I figure you are familiar with at least a few of the 'draw backs'. Unless there's something really 'different' about your new home, it should work about as well as it did in the old place, maybe better, maybe not. There's not much anyone can say about how well it will work until you try it. Good luck...

> phenomenon--what happens to the energy, or power in the reflected waves on
> return to the match point.

Well, once Steve admitted that the two reflected waves completely cancel each other in a matched system, what happens to the pre-existing energy in those two waves before they cancel is obvious. Energy cannot be destroyed and if it doesn't flow toward the source, it must flow toward the load as explained at the bottom of the Melles Griot Web Page:

http://www.mellesgriot.com/products/optics/oc_2_1.htm

"Clearly, if the wavelength of the incident light and the thickness of the film are such that a phase difference exists between reflections of p, then REFLECTED WAVEFRONTS INTERFERE DESTRUCTIVELY, and overall reflected intensity is a minimum. If the two reflections are of equal amplitude, then this amplitude (and hence intensity) minimum will be ZERO." (emphasis mine)

"In the absence of absorption or scatter, THE PRINCIPLE OF CONSERVATION OF ENERGY indicates ALL (rearward-traveling) "LOST" REFLECTED INTENSITY will appear as ENHANCED INTENSITY IN THE (forward-traveling) TRANSMITTED BEAM. The sum of the reflected and transmitted beam intensities is always equal to the incident intensity. This important fact has been confirmed experimentally." (emphasis mine)

Steve at first said the energy in the canceled waves continues to flow toward the source without a voltage and current and that interference was not involved. He later changed his mind. All that should be archived on r.r.a.a on Google for the summer of 2001. Here's an excerpt. Steve said: "The total forward power increases as a direct result of the vector superposition of forward voltage and current. This DOES NOT require a corresponding destructive interference process ..." thus contradicting Hecht in _Optics_ who says any constructive interference process must be accompanied by an equal magnitude of destructive interference.

> Now to continue what Steve said is: "The result of this
> wave cancellation is that the total steady-state rearward-traveling wave has a
> net voltage of 0 V nd 0 A, respectively, and an impedance match occurs." No No
> No.

> As we've discussed earlier, voltage and current cannot both go to zero
> simultaneously, except in the rearward direction.

But that's what he said above. The rearward-traveling wave indeed does have a net voltage of 0 V and 0 A and the reflections toward the source disappear at the match point. I think you and Steve really agree on about 98% of this match point stuff but you two obviously disagree on the definition of "re-reflection".

> I know you don't agree with me that a one-way virtual short is what causes the
> re-reflection, but in a short time I'll be able to prove it to you in a manner
> you'll not be able to rebut. Stay tuned.

You might want to check your work against an s-parameter analysis. The s-parameter equations are: b1 = s11(a1) + s12(a2) and b2 = s21(a1) + s22(a2)

Given that a match point in a transmission line can be considered to be a two-port network, |s22|^2 is the Power (re)reflected from the network output divided by the (reflected) Power incident on the network output. s22 is the reflection coefficient looking into port 2 and is *not equal to 1.0 or zero*. In a matched system with nothing but resistances, it is often the negative of the reflection coefficient at the load.

This is covered in HP's AN 95-1 available on the web.

> Those who don't believe will get quite a surprise when I reveal what the output
> source resistance of the xmtr really is under this condition. Waddya think?

I think I am too ignorant of the subject to venture an opinion. Which of the following systems do you think I would prefer, the conjugately-matched one at 50% efficiency or the non-conjucately one at 98% efficiency?

1 ohm XMTR----100V out---tuner---1/2WL 450 ohm line--50 ohm load

50 ohm XMTR---100V out---tuner---1/2WL 450 ohm line--50 ohm load

Arguing that Tesla/Westinghouse would have to conjugately match their 60 Hz AC generators is what shot down Edison's dream of an all DC power distribution system for the USA.

I would love to have a transmitter with a zero ohm internal impedance, completely conjugately unmatched. :-)

Given a single dipole, multi-band antenna, parallel transmission line
is just about the only choice. The 50 ohm SWR on a one-wavelength
dipole is about 100:1. The 500 ohm SWR on a one-wavelength dipole is
about 10:1. Under those circumstances, it is no contest.

I would love it as well!

:-)

I fear that Walter is far too hung up on that conjugate match stuff...
Walt, you need to move
on to more important things. Don't continue to fuss with others over such a
trivial and ultimately
unimportant point. Have you left for the North yet, or still in Deland?
Sorry I've been far too
busy with consulting to get over to see you this past winter.

BTW, Cecil...

Faced with the possibility of owning such an ideal transmitter and given the
choice...

I wonder, considering the condition of most amateur antennas... which you
would love better in practice...

A completely mismatched zero Ohm impedance voltage transmitter

-OR-

A completely mismatched infinite Ohm impedance current transmitter.

> for 70 cm.
>
> What is type of coax should I use? Rg213? Or will RG213 be too lossy?
>
It depends on what you wan to do . As mentioned use the lowest loss you can afford. The 5/8 inch hard-line is great but not many will want to pay the $ 5 per foot and about $ 70 per connector and put up with the stuff not being easy to bend.

Look at the LMR 400 or Belden makes some that is hard to find I think is called 9914. It has almost the same low loss as the 9913 but uses a solid dielectric instead of the hollow type of the 9913. If you are only using 30 or 40 feet and mostly the FM repeaters, the RG8x type is ok. As someone mentioned the RG 6 type sold for cable TV is fine for a run of 50 feet or so. The on;y problem is the connectors. IT is 70 ohm coax but for most simple systems it will not mater.

I have used most all of the above but the hard-line at home and it all depends on what I was doing. I only want a few local repeaters for a rig in the house so a homemade dipole (vertical) is up about 25 feet on the tower. It has about 40 feet of rg59 and then about 30 feet of rg58 going to it. Not the best but it works fine for what I am doing. I also have a 2 meter ssb rig in the shack that is fed with the 9913 and it seems to work ok for it. Using a dual band antenna to a scanner that is programmed with 2 meter and 440 repeaters and feeding it with about 100 feet of rg8x. The 2 meter part works great but not so good on the 440 band.
The satellite antennas are feed with the 9913 and sofar I have been able to keep the water out of the coax.

A folded dipole as the driven element will have the best match over your
frequency range..

What you do have to worry about is the feedpoint resistance. Some Yagi-Uda
designs are expressly designed for (a driven) folded dipole, which in isolation
have a much higher feed resistance than 50 ohms. When you put parasitics in the
near field, in certain gain-optimized Yagi-Uda designs, that feed resistance
falls closer to 50 ohms.

Typically, a non-matched regular dipole as driven has a feedpoint resistance of
much less than 50 ohms in a high gain Yagi-Uda app. Thus you may be seeing 1-2
dB or mismatch from this lower feedpoint resistance. Or you can make a T-match
(for example).

If you have s specific design that uses a folded dipole, I suggest you stick
with it. Unless you want to eat a dB or 2 in possible mismatch, or put a
matching system in on a conventional dipole as a driven.

Offhand, it would seem feedline radiation is ruining the pattern. Skews
the pattern up off the horizon. Not that your coax length is nearly a
1/2 wave now. It's probably acting as part of the antenna. Try a
choke, ferrite beads, etc, below the feedpoint. MK

Just a note: it is illegal to engage in shortwave "broadcasting"
without a license.

You might subscribe to some of the shortwave magazines, to get a feel
for things.

And, also subscribe to QST if you're interested in ham radio.

Best of wishes...

Bob

For around $400 you can get a used Icom IC-R75 and if you're thinking of being a ham look at the IC-718, pretty much same Rx except no coverage above 30MHz. Yaesu FRG-7 is a decent analog Rx.

Richard, I'm sure you have a specific reason for a direcitonal marine antenna, but just for others who like the sound of that idea... unless all your marine band traffic is DX from a relatively narrow range of direction, the beam antennas for marine are more trouble than they are worth in my experience. I wasted a lot of time spinning the rotator around 359 degrees with various directional antennas and finally scrapped them all. Even considering that most beams can hear front and back, more than 10 degrees to the side(s) and they are deaf by design. A great design popular with amateur radio and a superb performer on marine-band is the copper pipe J-pole. Tuned right on center 156.800 Mhz, I have yet to see a vertical hi-gain whip outperform this setup (probably because factory whips are so far off-center). I have over 100 miles coverage of USCG high-sites and approximately 15 miles coverage from on the water small craft with a J-pole. My antenna is mast-mounted on a 2d story chimney, and in spite of some erroneous construction advice, it is grounded (well!). The blunt-tip copper pipe cap on a J-pole is the ultimate lightning rod, and #4 or heavier conductor to at least an 8' ground rod is highly recommended.

Go on ebay and get yourself some 1/2 andrews hardline.
Ends are not much money for N, so239 are more pricey.

If you cant, get some LMR400.

www.cablexperts.com are good people.

don't quote me on this but some commercial guys put up a run of LMR400
(don't remember the legenth but was 200-300ft) and even this the antenna
gain it was a negitive db number at the top.. this was at 450mhz.
so i know we are talking about a long run there but i still don't think
LMR400 is great..

For about $400, you can buy any of the following on the used market
(ebay) without working too hard at it.

ICOM R70a
ICOM R71A
Icom R75 (cutting it close, but you can probably find one for less than
400)
JRC NRD525 (again, cutting it close, but on SSB it's the best of this
bunch). The best ergonomics by a mile. Needs an external speaker, dont
bother with the JRC ones, just use anything available, it will at least
equal the 525's matching speaker. This thing was almost 1200 bucks new.

Yaesu Frg7700 I would put this a notch below any of the above.
Yaesu Frg8800 This one too.

BDK

Superposition of forward voltage and current? I didn't realize that voltage and current superpose. But if Steve says so. I agree on the interference, but doesn't the destructive have to occur before there can be constructive interference?

>> Now to continue what Steve said is: "The result of this

>net voltage of 0 V and 0 A and the reflections toward the source disappear at
>the match point. I think you and Steve really agree on about 98% of this match
>point stuff but you two obviously disagree on the definition of "re-reflection".

I don't recall Steve ever mentioning current. He simply says the voltages cancel, resulting in 0 V. What Steve apparently doesn't understand is how the energy direction is reversed when the rearward voltages and currents go to zero. Since the energy cannot go to zero what happens at the match point is that the E fields go to zero and the disappearing E field energy merges into the H field energy, raising both the H field energy and its associated current to double their values relative to those prior to re-reflection. The energy now propagates forward and the E and H fields resume their normal relationship, half the total energy in each. This is precisely what happens to the EM field when it encounters a physical short circuit. But in our case the reflected EM fields encounter a virtual short circuit, with the same result as with a physical short except that the virtual short to the reflected waves is transparent to the source wave.

>> I know you don't agree with me that a one-way virtual short is what causes the
>> re-reflection, but in a short time I'll be able to prove it to you in a manner
>> you'll not be able to rebut. Stay tuned.

As I said above I'll prove to you conclusively that the virtual short circuit is established by the wave interference, contrary to what you and many on this rraa thread believe.

>
>50 ohm XMTR---100V out---tuner---1/2WL 450 ohm line--50 ohm load

Cecil, your comparison above lacks logic. Your are assuming that the XMTR is a classical generator, where the maximum efficiency cannot exceed 50% because the internal resistance is dissipative. OTH, the souce resistance at the output of the XMTR is non-dissipative, in which case it wouldn't matter which of the two XMTRs you choose. The only dissipative resistance in the amp is that which heats the plate. That dissipation is the only dissipation in the source--the other dissipation is only in the load. If you don't agree with this concept please review Chapter 19 in Reflections 2. I also have other measurements that prove the concept is true.

Well, the average ham with a mighty 40-watt soldering iron and rusty
pliers isn't going to do much better. At least the minimum wage guys
are probably making cables with good tools -- 120-watt or better
Weller irons with 1/2" tips, etcetera...

I spend just about eight hours a day lately at a factory where cables
and other stuff are made. Every day when I walk through the
cable-making section, I think to myself "wow, I wish I could use those
tools for my own nefarious purposes". The tools are expensive and
pretty high-quality, but the employees see them as just... tools.

Jack.

3245. Antenna Question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-05-31 19:32:56 UTC
From: dan_hoffard@hailmail.net
Message-ID: <648fff84.0405311132.2448e399@posting.google.com>
Source record: 94250

I have a dipole in the attic tuned to around 14Mhz. Whenever I
transmit at full power, the laptop sitting next to my rig goes crazy
and the light in the next room turns on (its hooked up to a clapper).
When on 80 meters, if I transmit at full power and use my antenna
tuner to tune near perfect SWR, the treadmill in back of me turns on.
Is this normal? Should I worry about excessive radiation?

Thanks,
Dan

Is this normal? Yep!

Should I worry about excessive radiation? Nope!

You have RF coupled into the power lines. You need some type 43 clamp on ferrites to solve the 'normal' RF susceptibility of those components.

If you don't think lmr 400 is great, what do you think is that is in the same size ,type, price range ? As far as I know it and the 9913 type have the lowest loss for the nominal 1/2 inch size flexiable coax.

There is some other coax types such as lmr 600 (think that is the number) that is some what larger and takes other more expensive connectors than the more comman types of pl259 or type N connectors.

Adair,
You can get slightly different numbers from different sources, but from the
CableXperts chart, the loss in 300 feet at 450 MHz would be 15.6 db for 213,
8.4 db for 9913, and 8.1 db for LMR400. For comparison, garden variety RG8
foam is 14.1 db, and 1/2 inch Heliax 4.5 db. Clearly, none is acceptable
without an antenna mounted amplifier.

Whenever I think about a simple VHF wideband omnidirectional vertical antenna for my marine band listening, I'm always thinking folded dipole. I think I've got folded dipole on the brain. But wait - isn't it better to make J-pole. Constructionaly simpler I think, and you can feed with unbalanced coax. Are J-poles wideband antennas? I want any antenna to cover 156-162 MHZ (6Mhz bandwidth) - RECEICE ONLY. Would a J-Pole do here, bandwidth-wise?TIA.

A search on google found this marine J-pole.

http://www.arrowantennas.com/j-pole.html

Looks well put together, and covers what you want at 1.5 to 1 claimed.

Receive only antenna shouldn't be nearly as critical as x-mit. fat tubing (say 1/2" copper water tubing) will be wider band than say 1/8" brazing/brass wire.

A search for 2 meter J-pole or VHF J-pole will turn up a lot of amateur/ham antenna designs, just shorten the lengths to 146 MHz / 159 MHz (0.92) times the published lengths.

You also can make a 1/4 wave ground plane antenna w/ a SO-259 (UHF) connector (or other flange mount RF connector) and a 17 1/2" (about) piece of brazing wire or small tubing vertical in the center lead solder socket and 3 or more (4 is easest) 17 1/2" wires attached to the coax shield grounded mounting flange and bent downward 45&#65533; or so. Google for home made ground plane antenna (and/or 1/4 wave, 2 meter, VHF, etc.) again scale 2m dimensions by 0.92

Performance for either should be similar, again the fatter the element diameter the broader the bandwidth, but for receive it is less critical than for transmit.

http://www.hamuniverse.com/jpole.html This is the directions for the J-Pole
of copper pipe that I use very successfully for 2-way marine band traffic.
It is centered on 156.800 and works great over the whole marine band. I do
not use any form of choke on it, and feed it with RG-8U through a I.C.E
Lightning Arrestor from a JRC marine transceiver. Ground it well.

|A folded dipole as the driven element will have the best match over your
|frequency range..

Unless of course it doesn't.
|
|What you do have to worry about is the feedpoint resistance. Some Yagi-Uda
|designs are expressly designed for (a driven) folded dipole, which in isolation
|have a much higher feed resistance than 50 ohms. When you put parasitics in the
|near field, in certain gain-optimized Yagi-Uda designs, that feed resistance
|falls closer to 50 ohms.
|
|Typically, a non-matched regular dipole as driven has a feedpoint resistance of
|much less than 50 ohms in a high gain Yagi-Uda app.

Unless it doesn't. For the example I offered earlier:

Freq R X VSWR Gain F/B dB

156 51.50 1.97 1.050 9.95 14.34
157 50.12 2.77 1.057 9.99 16.43
158 49.34 5.22 1.112 10.04 19.20
159 50.38 8.31 1.180 10.08 23.41
160 54.16 9.95 1.230 10.10 30.84
161 59.78 5.68 1.229 10.07 28.01
162 57.99 -8.24 1.237 9.96 21.35

Oh, for heaven's sake. Sodium is easily handled if you are familiar
with the stuff. Keep it under Kerosene.

Don't get it near water and do not get it against bare skin.

OTOH I've taken *small* pieces/slivers of it and dropped it on water
as a demonstration. They skate around as if they were on ice, but
popping like tiny firecrackers.

Larger chunks into water would not be smart. It generates heat,
Hydrogen, and Oxygen. The Sodium is hot enough at the water interface
(at least to start before it gets hot) to ignite the Hydrogen/Oxygen
mix making the popping sounds with the little slivers.

In high school chem lab we used to get to play with Sodium and
Phosphorus. Now days they wouldn't even do the demos and as kids we
were able to do them ourselves.

Well, Cecil's classmate must have been a prime candidate, with his original idea about flushing a large lump down the toilet. Can't you see him, arriving at the Pearly Gates, still clutching the flush lever in his hand...

>Sodium is easily handled if you are familiar with the stuff.
[...]
>Don't get it near water

On the north coast of Scotland there used to be a nuclear power reactor that was cooled by molten sodium. On the other side of the main heat exchanger was high-pressure water, separated by the thinnest possible sheets of metal. The guys who operated the heat exchangers used to complain about that highly corrosive liquid... but they were talking about the water.

Sorry I'm a bit uncertain of what you wrote.

Obviously an efficient way to provide data for yagi's, but how do you read
it?

Is there a webpage associated with the design, so I can look at the general
construction?

Rich.

This looks like a modofied approach to an NBS Yagi-Uda.

Modern Y-U design allows for a higher feedpoint SWR. Matching loss is offset by higher gain and better consistency of F/B. If no matching, then a shaped, folded dipole is used. Typically a F/B better than 22 dB (sim) is acheived with a 10% bandwidth.

The design you discuss sounds more than adequate for this need though, in fact most needs.

The only special feature of the NBS designs (other than the prestigious mailing address) was a self-imposed restriction to equal spacings between directors. That turned out to be an evolutionary dead-end, and you won't find it in any modern optimized yagi design.

The design proposed by Wes doesn't have that feature - fortunately - and is actually one of the OWA (Optimized Wideband Array) family. One of the special features of that family of yagis is a very close spacing between the driven element and the first director, which raises the feedpoint impedance to 50 ohms and allows a simple split-dipole driven element.

Even this feature is not original to the OWA family. I don't know when (or indeed how often) it might have been invented, but it was first systematically used by DL6WU some 25 years ago. With additional help from computer analysis and optimization, the OWA family continued the development.

>
We're now in the excellent position of having several alternative ways to design a yagi to meet each user's specific combination of requirements. That approach is certainly one of them.

Dan, you're (relatively) safe, but your household electronics may be in danger <G>...

You might want to look at RF grounding, or try changing the lengths of your dipole or the feedline (assuming it is coax?) . You might not fix all your problems, but you can alleviate a lot of them. The rest comes down to quality of design of the devices you're turning on...

```

This is the format for almost any of the common antenna modeling programs. See for example:

Free:

http://www.qsl.net/wb6tpu/swindex.html (look for files beginning 4nec2)

Almost free:

http://www.qsl.net/ac6la/multinec.html

Free demo:

www.eznec.com

etc.

With a fixed width font, the columns would line up and each line would represent one element, starting from the rear (reflector end) of the boom. The data are the X,Y,Z coordinates of the ends of the elements and the diameter of that element. Z is this case is zero since the model assumes free space. It also assumes no effects from the supporting boom; the usual compensations must be made for this, depending on the element mounting method. See:

http://www.antennspecialisten.se/en/ham/tech/bc.html

I assumed that you had some experience with Yagi design and construction and were simply looking for a design that gave both the required bandwidth and a fifty-ohm feedpoint; something this design delivers.

I can easily be mistaken, but I don't believe the NBS Yagi designs were ever promoted as being optimal in any way. Their purpose, I believe, was to provide a set of easy-to-duplicate designs whose gains were well documented (although I understand an error was made in measuring the originals) and which anyone could construct as reference antennas with known gain.

I agree, none of those are great numbers by any means. i honestly don't
remember the specifics of it all, it might have been 800Mhz at 100 ft.. i
just know that I whoever had put it up wasn't impressed with it.. (didnt'
live up the posted specs) and i do believe the loss was verified with an
IFR..
anyway.. i prolly should have kept my mouth shut not knowing everything in
detail.

They were in fact described as "optimum designs" in the original paper, but it's clear that claim was made subject to a number of reservations. Most of the hype came from antenna manufacturers who subsequently picked up the designs from the published reports, and misused the "NBS" name to boost the credibility of their own products.

With hindsight, the NBS designs were really quite good, and their forward gain is still competitive with more modern designs of the same boom length. But modern yagi designs are generally better, because there have been a further 35-40 years of development and optimization. In particular, the last 10 years have benefited from the availability of computer modeling techniques - you can now do more good work in a few evenings than the NBS program achieved in as many years.

As a result of this development, you can now have a better combination of features - for example, cleaner patterns, wider bandwidth and/or greater tolerance to dimensional errors, and easier impedance matching - and keep the good forward gain as well.

Many modern designs have been developed as complete 'families', with simple design rules that let you add or remove elements (changing the boom length accordingly) to create new yagis, each of which will be close to optimum for its boom length. The NBS yagis don't have that 'family' feature - each one is an individual design, and attempts to adapt them have generally not been successful. This lack of adaptability is a direct consequence of the original decision to use the same spacing between all elements; that's why I described it as an "evolutionary dead-end".

It costs exactly the same to build a good, modern yagi as it does to build an older, inferior design - the only differences are in *where* you apply the hacksaw and the drill. Therefore there's not much point in building an inferior design... which is what the NBS yagis have now become.

For many years, the greatest value of the NBS yagis was that they had accurate gain measurements, so they could be used as reliable benchmarks

in antenna gain shootouts. (The known error in the gain measurements applies to the 2-element yagi only.) Even that use has now been overtaken by computer modeling.

In summary, the NBS yagis deserve respect for their major contribution to the art and science of yagi design, but they are now mainly of historical interest.

For examples of modern yagis, and tips on construction, see the 'VHF/UHF Long Yagi Workshop' on my website.

I respect your opinion, but the question did not say 'multiband' antenna.
I used belden 300-ohm twinlead for 2-meters because I had a long run to the top of a tree on the other side of the yard. The specs showed it to be low-loss at 2-meters. The cost was affordable - much less than low-loss coax.
So I used a u-bent half-wave piece of coax on each end and a 1/4-wave of 75-ohm coax with it - and it performed very well in the real world and the impedence match was good.
I even had the project published in the Antenna Compendium a few yrs back.

I've used it with success - recently. 450-ohm window-line (has copper-clad steel conductors, so its tuff)
then on each end: a combination to match impedence - a 75-ohm 1/4-wave stub (goes from 50 to 112.5 ohm) then a half-wave u-bent setup (112.5 to 450 ohm)
see page 165 of Antenna Compendium vol 6 for a better description - I wrote that article back in 1999 or so.
I've also used similar setups and 300-ohm belden twinlead.
It may be a myth from the olden days, but 2+2 still equals 4 - just like the old days. And its not a myth - it really does work.

De-ionized water wants ions and it'll take them from any available
metal. It's particularly corrosive with brass. We had a series of
induction heating units that used high power RF. The tubes and coils
were cooled with de ionized water. A brass hose barb would crumble in
your hand after only a years exposure to the di water.

On the contrary, you asked me to prove a negative, a logical
impossibility, e.g., prove that you have never robbed a bank.
Not getting caught is NOT proof.

OTOH, all I am asking from you is one measly example out of the
multitudes of your postings in which examples have been alluded.
If I paid you $100, would you please produce such an example?

Sorta begs the question, why don't you just turn your 718 power
control down to qrp levels -- the 100 watts are still there, should
you need them later.

Also begs -- why trade a $600 Icom for a $400 Patcomm?

Also, is Patcomm in business nowadays?

Well, I am relatively new to cw so unaware of what filters there out there and what things may be packed into a certain rig. The pc-500 may only have 15watts, but it could be optimized for cw. The icom may have 100 watts and cost more, but it is still entry level. I can actually be cleaner with my rockmite 20 @ .5 watts and not get any qso's with my icom at 50 watts. But propagation could have changed. The K1 is packed with cw stuff that I have no clue about would like to learn as qrp is a lot of kit building and homebrew and a wealth of knowledge is necessary.

Thanks

FWIW, the Patcomm is also just a 2-band rig.

If you are an ARRL member, you might look some of these rigs up in the
Product Reviews Section of the ARRL website -- they do a pretty good
job of laying out what a rig will do in CW and other modes.

Frank,

I followed up with the US company that served as the US importer and
distributor -
they sold last stock in early 1990's at Dayton hamfest.

I still have an interest in finding a skeleton slot antenna (J-beam) for 2
meters and 70 cm -
that my VHF Elmer in Hamilton, IL had. Alas, I am sure one of the local
amateurs purchased it ---
and the only plans are from the RSGB VHF-UHF Handbook - 1970s edition

Speaking of tips . . here's one. I've never been happy with any of the
Weller irons, not even the clunky big 300W versions when it comes to
"doing" PL-259s. Turns out that Sears has a very light and compact
transformerless pistol type "instant heat" 400/150 watt iron which I
bought for $59.95 about a year and a half ago. Does a great job on
connectors and heavy antenna wire.

I've never been happy with monster irons either, but have had very good results using a hot-air gun as 'pre-heat' for my regular 45W Weller.

It's very easy to judge how long to pre-heat the whole connector body. Then the regular small iron has plenty of power to make a good, clean joint in the solder holes. The same technique is also good for fine soldering work on large lumps of metal.

The bonus is that a hot-air gun is much cheaper than a large iron, and you can also use it for other things too, like heat-shrink tubing. (Did somebody mention removing old paint? What's this "paint" stuff? :-)

It isn't a technique to use at the top of a tower... but there isn't *any* good way to do heavy soldering under those conditions. For that kind of application, seek out the pressure-sleeve connectors that only require the center pin to be soldered.

What frequency? What length? What loss did you measure? Was it raining?

Of course twin-lead can "work" in a wide range of applications.

The myth is that it can beat a modern coax cable at VHF, on a long run
with practical installation difficulties, and in the rain.

Vicious stuff, that water.

The added problem with tube power amplifiers is that there's usually high voltage around. DI water is a good insulator, but if there are enough ions in solution the leakage current will cause electrolysis... which dissolves more metal ions, and then the whole system goes rapidly downhill.

According to an article by N6CA (which was in the ARRL Handbooks for some years) the secret is to monitor the DC leakage current, and change the water when the current starts to creep upward. Modern plastic components help a lot, by minimizing the total area of exposed metal.

I have a assortment of antenna that I can use for listening .The one
that I get the best Reception on is a 5/8 wave groundplane, feed with
RG-59. I put my MFJ antena analszer on it and and the SWR was nearly
flat all the way across (123 Mhz to 172 Mhz) this year I have things
set up o I can hook two scanners on to the one antena. One thing I
would advise, If you are gonig to cooper in your construction, give it
a coat of trimcald. I ended up doing some high level repairs to my
antena . The groundplane element had a a greenish ttimg to them after
on one year of being exposed to the elemts(weather).

3297. indoor 2m antennas

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-02 07:54:34 UTC
From: Jim noname <asdf@asdf.com>
Message-ID: <SIfvc.34985$eY2.14267@attbi_s02>
Source record: 94152

hello. I just had a few questions about building 2m antennas.

This will be used indoors. I havent decided if its worth the trouble to climb around in the attic or if I should just mount it on the wall. I have vinyl siding so hopefully that is a plus.

My first is about the classic ground plane built on a so239 connector. I went with #14 wire and soldered the center wire on no problem. My question is whats the sturdiest way to stick on the radials? I have a 100 watt iron and still can't get a solid connection for the radials.

I was also considering just putting up a vertical dipole on the wall. I've heard people say they had better luck with the ground plane but maybe they didnt have the coax ran off to the side far enough or just dropped it straight down? It seems a little tricky feeding it from the center and having the antenna vertical but maybe a few wire tacks can fix that.

As a alternative to the dipole on the wall I also thought about just getting a connector and soldering the wire directly to it bent upwards and then using some flexible wire for the ground and let it hang below the shelf. Would this work ok being connected directly to the radio?

What do you guys suggest?

thanks

See the message in another thread, about using a hot-air gun to pre-heat the connector before applying the iron. That'll do it.

#14 wire will tend to sag under its own weight, so it's better to use thicker copper wire like #12. Some designs show the radials attached with solder-tags, but in my experience they bend. It's better to crimp radials through each of the four holes in the socket, and then solder them on directly. Cut the radials to their final length *after* you have completed the crimping and soldering.

There may be a problem with soldering to some kinds of plating, so choose a connector made from brass as the base material. Drill the surface plating out of the four holes, and also file it away around the corners so you're soldering to bare brass. Also pre-tin the four corners with solder before you crimp on the heavy wire radials. Then it will solder easily.

If the SO239 doesn't have teflon insulation, screw on a PL259 to keep the center pin from moving when the insulation softens, and leave it to cool down before you remove the plug.

Finally, be aware that the feedline needs to run straight down through the four sloping radials and some way beyond. If you notice any weird behavior, it's probably due to RF currents on the surface of the feedline - this type of antenna is quite prone to that problem. Two large ferrite beads clipped onto the feedline will probably fix it; use one right behind the PL259, and a second one about 19in down.

Having said all that, any 2m antenna will work much better outside! If you're tied up in CC&Rs, take a look at the Ventenna concept for a well-disguised outside antenna.

That's clever, I have a heat gun (somewhere), I'll try it. Sounds like
the method might reduce the total number of BTUs/calories absorbed by
the dielectric which has always been a concern here. Barbequed coax is
very annoying.

Jim,
If your soldering iron isn't 'heavy' enough you can always
use a few bolts to attach the radials.
Another options besides the walls and desk top is the
ceiling,
hang the antenna from a hook. Or, if you're feeling
adventurous,
draw the antenna on a large sheet of paper with a graphite/lead
pencil, tape it where ever you want. Or use 'burglar alarm'
tape
on a window.
As Ian said, the 'best' option is to put the antenna
outside...

I'm sure he meant "superposition of forward voltages and superposition of
forward currents."

> I don't recall Steve ever mentioning current.

I think you are right re his article. The above quote is from an
r.r.a.a. posting circa Summer 2001.

> What Steve apparently doesn't understand is how the
> energy direction is reversed when the rearward voltages and currents go to zero.

"How" is not explained in any of the physics references. The closest
physics reference that explains it is _Optics_, by Hecht where he says
something like, at a point some distance from a source, constructive
interference must be balanced by an equal magnitude of destructive interference.
In a matched system, there is "complete destructive interference" toward the
source side of the match point and "complete constructive interference" toward
the load side of the match point. Energy is always displaced from the "complete
destructive interference" event to the "complete constructive interference"
event. (That's what you call a "virtual short" or "virtual open" capable of
re-reflecting the reflected energy.)

In s-parameter terms, b1 is the reflected voltage from port 1 toward the source.
Port 1 is the input to a matched tuner (transmatch). The equation is:

rearward-traveling voltage reflected toward the source b1 = s11(a1) + s12(a2)

For b1 to be zero, i.e. zero reflections toward the source, s11(a1) must be equal
in magnitude and opposite in phase to s12(a2). That is "complete destructive
interference". Since there are only two directions, "complete constructive interference"
must occur in the direction of b2 = s21(a1) + s22(a2) toward the load which is the
opposite direction from b1.

s11 is the port 1 reflection coefficient. a1 is the port 1 incident voltage.
s21 is the port 2 to port 1 transmission coefficient. a2 is the voltage
reflected from the load that is incident upon port 2.

Match-Point
Port1 Port2
Source------Z01--------x------------Z02------------load
a1--> <--a2
<--b1 b2-->

> The only dissipative resistance in the amp is that which heats
> the plate. That dissipation is the only dissipation in the source--the other
> dissipation is only in the load.

Why isn't the source impedance a negative resistance, i.e. a source
of power Vs a positive resistance, a sink of power?

I had a 1/4 wave 2m GP in the attic, built around an SO239 connector. Worked like gangbusters. I later put up an Isopole outside, but in some directions the attic antenna worked better.

Don't try to solder the radials on to the connector. Get 4 spade lug or ring terminals, and solder one to each wire. Fasten to SO239 with the mounting screws. There is no wind in the attic; so you can use soft #16 wire if you want. You can either put an insulator on the top of the vertical and hang it from the peak of the roof, or nail a vertical piece of wood up from the rafters. For the latter, fasten some sort of horizontal plate (wood, plastic, metal) to the top, and mount the SO to that.

I would not tack the vertical dipole to a wall. Put insulators on the ends, and run it between the rafters and the peak of the roof. You need to run the coax at right angles to the dipole for as far as possible. Taping the dipole to a thin piece of dry wood, or piece of plastic pipe might be OK.

I was able to bring up repeaters 60 miles away with 10W using the attic GP.

Bingo, I was going to say the same thing.

It doesn't matter if your radials are droopy or not.

That's an excellent antenna for the attic.

Now you are on the air, here are a few more to look at !

http://www.cebik.com/hs.html
http://www.cebik.com/mvhf.html
http://www.cebik.com/moxbld.html

all are direct fed with 50 ohm coax and low cost.

I've made several of these that work well from an SO-239, and coat hangers. Talk about cheap, but they work well anyway. The coat hanger radials are stiff enough to support themselves, and after sandpapering off the paint down to bare metal, they solder OK directly to the SO-239. The radials should be slightly longer than the vertical section and slope down at roughly a 45 degree angle. Of course, if the antenna is outside, it will rust. But if it's indoors, no problem. Also, I soldered a spade lug to the top of the vertical section allowing me to hang it from the center beam of the roof on the inside of my attic.

In fact, you want them to droop! About 45 degrees droop will give 50 Ohms
impedance, which you can't get with a dipole.

the 'classic' method of doing a vert dipole is to use a copper pipe for the
lower segment, and running the coax up to the antenna through the pipe. I
built a 6 meter vert dipole that way.

My suggestion however is a j-pole , either in the attic, or you can
literally hang it from a wall.

I built one guy one on by hot gluing an 16 gauge bare wire to the back of a
plastic poster holder in the correct dimensions, all you see is the RG-58
coming down out of it. The hardest part was getting the cable supported
properly.

Mine (made from 12 gauge solid copper) is tied onto a support beam in the
attic with nylon wire ties, and the feed line runs off horizontally, the
choke coil supported on the next beam.

Cecil, I explained the 'how', both in Reflections and in QEX. My explantion of 'how' is what Steve is continually stating is incorrect, especially in his last 3-part QEX article. Statements in that article prove he doesn't understand the wave mechanism that reverses the direction of the reflected energy. Evidence of this is that by simply saying the voltages cancel is insufficient description of how the energies reverse direction. In fact, in his Oct 99 ComQuart article he specifically states that both voltages and power cancel. This tell me that he

doesn't understand the wave action he's attempting to teach.

MIT's Slater and Harvard's Alford both explain it brilliantly, but Steve rejects those references as 'irrelevant', and says I mistakenly used them as references in Reflections.

What is really perplexing to me is that several posters on this subject said that Steve's 3-parter is the best and most illuminating article they ever read on the subject. How can they have missed some of the most egregious errors appearing in that paper is unbelievable!

>opposite direction from b1.

Cecil, if s11(a1) is equal in magnitude but in opposite phase with s12(a2) this constitutes a short circuit. Assume two generators delivering harmonically related output voltages equal to the two 's' voltages. When the generators are connected with their output terminals reversed, causing their voltages to be 180 degrees out of phase--this configuration is a SHORT CIRCUIT. What I've been trying to say is that this is the same condition as when the reflected waves of voltage and current from a mismatched termination are of equal magnitude and opposite phase with the voltage and current waves reflected by a matching device such as a stub, the opposing voltages in those two sets of waves constitute a short circuit the same as the voltages delivered by the two opposing generators.

>Why isn't the source impedance a negative resistance, i.e. a source
>of power Vs a positive resistance, a sink of power?

Cecil, the source impedance is often correctly referred to as a negative resistance. But it must be remembered that the source resistance of Class B and C amps is non-dissipative, and thus totally re-reflect incident reflected power. By this I mean that the dissipative resistance that heats the plate is entirely separate from the output resistance represented by the load line. Remember, the DC power goes to only two places: that which is dissipated as heat, and that which is delivered to the load. The reflected power incident on the output terminals of the tank has no effect on the power dissipated as heat.

Here's an example. First, adjust an amp to deliver 100 watts into a 50-ohm resistive load. Second, change the load to a reactive 50 + j50 load and readjust the pi-network to again deliver 100 watts into the new load. The plate current will be exactly as in the first case, and the heat dissipated will be the same. The difference is that in the first case the output impedance of the amp was 50 + j0, while in the second case the output impedance is 50 - j50, due to readjusting the reactive components in the pi-network to match the 50 + j50-ohm load. Whether one likes it or not, this constitutes a conjugate match.

As for the plate temperature remaining the same in both cases, first, the readjustment of the pi-network returned the input resistance of the network to the same value as in the first case. Thus the plates saw no different condition between the two cases. And second, Eric Nichols, KL7AJ, has measured calorimetrically the temperature of the water cooling the tubes of megawatt transmitters with greatly differing values of reflected power incident on the xmtr. He has shown that the water temperature remains constant whatever the value of the reflected power.

Since you mentioned earlier that some posters would like my opinion on the nature of the source resistance in rf amps I'll put a paragraph or two together with measurement data to support my opinion.

snip

Cecil, the following is a direct quote from Steve's Comm Quart Article, Oct
1999:
"For the impedance matching network to 'work', this analysis must demonstrate
that the steady-state traveling backward power developed at the matching network
input is equal in magnitude but 180 degrees out of phase with the initial power
reflected at the matching network input. For this to occur Vback must be the
negative of VR. In this case ALL POWER TRAVELING BACKWARD TOWARDS THE
TRANSMISTTER WILL BE CANCELED, resulting in the steady-state matched condition."

Emphasis mine.

You know, you could save yourself and everyone else a lot of grief if you would actually try to find even a single example of where I ever said forward and reverse waves don't produce a standing wave. Why would I say that, Cecil? Why do YOU make this claim? Why do you insist on putting words in my mouth? It's the one thing you and I have always agreed on - that, and interference in general. For cryin' out loud, man. We've got some issues for sure, but that ain't one of 'em.

Prove the impossible.

The deal is to replace someone's remarks with a ludicrous claim that you invent. Then challenge that person to prove the invented claim. It's impossible, so in a completely fabricated, fictitious and trivial sort of way, you win! It's as if a need to win had taken precedence over integrity.

It is perhaps worth noting that all the cute comments about cheap
materials and labor would apply equally well to nearly all the products
we buy these days. Who here makes all his own clothes and shoes,
for example?

As to cables, some sources (e.g., Cable Experts) seem to pride
themselves on good quality. And it would be a sad state of affairs if
they (and other professional cable makers), couldn't install connectors
much faster AND better than the typical ham with his motley hand tools.

Some exotic cable types are not even spec'ed for user-installed
connectors, by the way--even if said user is a competent electronics
house. Such cable types REQUIRE factory-installed connectors.
(This is NOT stuff needed by the average ham, fortunately.)

Notwithstanding all this, there are undeniably some junky, Chinese
ready-made cables out there. I bought a few from HRO, and about 20%
turned out to be bad. So now I will buy only the relatively upmarket
ready-mades (like Cable Experts). I notice that our local HRO seems
to be phasing out the no-name ready-mades; so I suspect I wasn't the
only one to have problems with them.

If you have an antenna with a swr that is flat over that large of a
frequency range , you are loosing much of signal in the coax. You can
probably take off the antenna and have about the same swr. If that is your
best antenna, you have much work to do on all your antennas.

Yep, that's one of Cecil's techniques, all right. It isn't used solely to win,
though.
It's more a means of making your opponent look ridiculous to those who haven't
been following the arguments. It's a dumb stunt that usually backfires, but,
hey!,
that's Cecil.

It's also worthwhile seeing what the cable looks like. A couple of years ago
I bought 100 feet of generic (Carol?) RG8 foam. Looked OK. Next time I
bought a 25 foot piece of the same brand with connectors. Well, when the
connector came off, I saw it was not the same cable; next to no shield.

Ralph, that was a pretty funny way of saying that RG-59 is suitable for 3' test leads only, never for transmission or receiving ;- 0 The differences realizable with RG-8U or 9913 would be amazing. For anything as high as high as 225-400mhz, hobbyists split hairs over a 1/2 db, and can never tolerate a 75ohm dummy load as a feedline. Down around 123 mhz, there would be slightly less difference. But a coat hanger fed with 9913 might do as well as a Yagi with RG-59! In order to operate during inclement weather, I had to add the losses from two connectors (with lightning arrestor) I didn't have when I used to disconnect and short to the ground bus. That had a noteable effect on vhf and uhf dx-reception. I have not tested dx-transmit since that installation.

Yes, you are probably getting RF'ed to death. I would try to use the lowest power necessary to carry on a QSO if you are using an indoor antenna. This is a common occurance with modern equipment with electronics in it. You might want to get the RF Exposure book from ARRL to assess your exposure to RF fields.

Hi Group

Can anyone give me a brief explanation of the theory of operation of a commerical FM broadcast antenna. Specfically the Jampro JMPC (picture at)http://www.jampro.com/fma/jampjmpc.htm It looks to me like a couple of 1/2 wave dipoles each folded into V and fed in phase using two gamma matches. If this is true I am puzzled by the tap point chosen. It seems further along the dipole than I am used to seeing, even considering that the feed for the dipole is likely 100 ohm. The feed must be very inductive. Polarization is stated as RH circular. How is this controlled?

|(hertz, folded) somewhere in 4nec2?

No, it's not specified as such. Modeling programs assume straight
"wires" so to model a FD you have to "construct" one from straight
wires. This is not trivial however, so don't try it until you
understand the pitfalls of "closely-spaced wires."

I strongly recommend that you download Roy's EZNEC demo, if for no
other reason than to get the excellent "Help" section.

|In the Geometry Edit I see "Radius" for wire diameter I suppose. Do I
|calculate the radius from the dia given in the table above? TIA.

Yes.

Also, when you get to building the real antenna, you have the problem
of how to feed the DE. The design in question offers a nice 50 ohm
impedance, but just opening the center and feeding directly with coax
is going to be problematic. In the Arizona desert where I live I've
gotten away with pigtailing the coax and using ferrite sleeve baluns.
Since this is a marine band antenna, I assume there's water around
someplace and that may be unsatisfactory for you.

What did you have planned?

Several years ago some friends and I tried mking some gain measurements on
quads. Found that more than about six elements did not help the gain of the
antenna to any useful degree. I would go with quads with fewer elements but
more antennas in your array.

Where did I go wrong in the following logic? You have said there is
no energy in those reverse-traveling waves. Waves cannot exist without
energy. Therefore, reflected waves don't exist. Since they don't exist,
they cannot cause standing waves.

It is often the result of me confusing the postings of
two people with similar names. It is also often the result
of logical deduction. For instance: Someone says, "Reflected
waves contain no energy moving past a point." Since waves cannot
exist without energy moving past a point, we can deduce that the
person has strongly implied that reflected waves don't exist.

Highly depends on the rods and what you have access to.

One method that may work for you is a bumper jack and a piece of chain
to the rods; if you can secure the chain to the rod, you can usually
jack them out far enough you can pull them by hand.

Usually its easier to just pound them down.

You went wrong in the first sentence. That statement is false. The second sentence is an over-simplification, and is logically dependent upon the first sentence being true. As a result the third sentence also has a faulty premise.

Not recognizing his power equations as classical EM physics interference
terms was a pretty huge mistake in Part 3. But alleged gurus on this
newsgroup have done the same thing. Apparently, power is simply ignored
in present-day transmission line theory.

> Cecil, if s11(a1) is equal in magnitude but in opposite phase with s12(a2) this
> constitutes a short circuit.

I agree it constitutes a "short circuit" for superposed rearward-
traveling voltages. But exactly the same thing happens to the current
as happens to the voltage. And an "open circuit" is what causes the
rearward-traveling currents to superpose to zero.

The two rearward-traveling superposing voltages might be:
(100v at zero degrees) superposed with (100v at 180 degrees)
The superposed sum of the two rearward-traveling voltages is zero.
This indeed acts like a short where voltages go to zero.

The two corresponding rearward-traveling superposing currents might be:
(2a at 180 degrees) superposed with (2a at zero degrees)
The superposed sum of the two rearward-traveling currents is zero.
This acts like an open where currents go to zero.

Or if you prefer, both the E-fields and the H-fields cancel to
zero when complete destructive interference occurs. In a transmission
line, it causes a surge of constructive interference energy in the
opposite direction, something you have called "re-reflection from a
virtual short".

100 watt rf generator driving an open, lossless transmission line. How much energy do you think moves past a given point along the line every second? 100 Joules, 200 Joules, or zero Joules?

What does "energy in" waves mean? Energy is required in order to generate EM waves. Energy can be transferred from one place to another by EM waves (if a conversion in form takes place at both places, or there is otherwise a change in the total energy at both places). And standing EM waves can store energy. But to infer that energy is being transferred from one place to another from the mere presence of waves could lead one to some wrong conclusions.

Tie a piece of chain around them and pull them loose with a car jack. Works
like a charm. You normally just have to get them a little loose and the
rest is easy. I've done it a few times with 10 ft copper clad steel rods.

Therein lies part of the problem with thinking that the unit
(Joules/sec) moves along a transmission line. Energy in Joules moves.
(Joules/sec) of power does not.

What the other people have suggested sound like good ideas for pulling a ground rod. Something that might make it a little bit easier before pulling them with the chain and jack is to put a pipe wrench on the rod and turn it in the ground a few times. That way the bond between the dirt and the rod is broken and it should pull up a little bit easier. In fact, while you are turning the rod, you might try pulling up on it a little bit at the same time like you are unscrewing it from the ground.

>Do they exist, or is it time to get creative ?

They do exist. I picked up a Larsen mag-mount base with a BNC
connector on it, at a local electronics store's parking lot sale last
year. I don't know what band it was originally intended for
(commercial FM band data-radio application, I suspect), but it handles
2-meter operation just fine with an HT rubber duck.

Getting creative (e.g. with a BNC bulkhead connector and a small metal
case) would also be fine.

Cecil, this is exactly what I've been trying to persuade you of, but always said
no, there is no short developed. But you must also agree that under this
condition the current doubles.

>The two corresponding rearward-traveling superposing currents might be:
>(2a at 180 degrees) superposed with (2a at zero degrees)
>The superposed sum of the two rearward-traveling currents is zero.

Of course, but the voltage doubles.

>Or if you prefer, both the E-fields and the H-fields cancel to
>zero when complete destructive interference occurs. In a transmission
>line, it causes a surge of constructive interference energy in the
>opposite direction, something you have called "re-reflection from a
>virtual short".

Well, Cecil, here's where we part company to a degree. Unlike voltage and current that can go to zero simultaneously only in the rearward direction, E and H fields can never go to zero simultaneously. At a short circuit the E field collaples to zero, but its energy temporarily merges with the H field, making the H field double it normal value. But the changing H field immediately reestablishes the E field, both now traveling in the forward direction. And yes, this is called re-reflection.

If Steve understands the action of the fields in the EM wave it's hard to understand why he finds it so erroneous to associate voltage and current with the their respective fields in impedance matching. Apparently he can't conceive that the voltages and currents in reflected waves can be considered to have been delivered by separate generators connected with opposing polarities.

3354. A horizontal "sleeve" antenna for 20m

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-03 20:07:33 UTC
From: hello <hello@nospam.com>
Message-ID: <SxLvc.49522$zm5.25179@nntpserver.swip.net>
Source record: 94109

HI
I want to put a dipole for 20m in my garden.
A tree and the home roof will be ok to fix the extremity.
My problem is the feed point : If IA center feed it , the feed line will just hang at the center of the garden, something not acceptable by the YL :-)

So I'm looking for a way to feed it by one "side".
I could endfeed it, but impedance matching is not so easy at such a high impedance.
Then, after reading lots of post in this newsgroup, I read about the sleeve antenna : generaly a vertical dipole where one leg is a sleeve. Coax enter in the sleeve to the center feed point.
I think this antenna could work horizontaly and for HF and solve my problem. Now, hanging horizontaly a 5m long metallic sleeve is surely not a good idea, but at HF , I thing that man could replace the sleeve by some wire cage.
So I end up with the idea of a cage or biconic dipole , with the coax entering horizontaly in the middle of the cage to the center.

What do you think of this idea ?
How many wire for the cage 2 (a bowtie), 3, more ?
Do you have a better one for my particular constrains ?

Lots of questions, but I'm sure you will have lots of answers !

Thanks in advance

Thierry

I remember my chemistry teacher dropping a small piece of sodium, perhaps
1/4" cube, onto his hand.

He was the only teacher I remember hearing swear and/or having flames
coming from his body.

> second? 100 Joules, 200 Joules, or zero Joules?

Equip the RF generator with a perfect circulator plus load and it is
easy to measure 100 watts out of the generator and 100 watts dissipated
by the circulator load. The 100 watts dissipated by the circulator load
makes a round trip to the open end of the transmission line and back
as can be proven using TV ghosting or a TDR. A Bird directional wattmeter
will read 100 watts in either direction.

So, to answer your question: There is 100 watts forward power and 100
watts of reflected power anywhere along that line. The *NET* power
flow is, of course, zero. I believe this is all explained in Johnson's
textbook under "forward power flow vector" and "reverse power flow
vector". I'm at work and don't have my references handy.

Hi Jim,

Of course you're right, but that's not the point. The point is that reflected energy is not canceled, nor does it disappear at the matching point, instead it is re-reflected into the forward direction. This is the point that Steve apparently doesn't understand. And this is the reason his power budget is incorrect in his 3-part article, he ignored the energy appearing at the match point, assuming that it disappeared, though his word is 'canceled'.

I thought my emphasis with capitalization would contain the necessary info, but I can see now that I should have made the emphasis show that the 'canceled energy' was erroneous, because energy cannot be canceled. In this case it is re-reflected, a concept Steve ignores.

Use two pieces of copper tubing for the elements. Connect one to the
center of the coax, the other to the braid. Bring the coax out through
the lower piece. This is also known as a coaxial-sleeve and a few other
variations on the name.

because that is not cecil's way, he will restate whatever is posed so that
he can answer it with his favorite discussion topics. any discussion like
this on here ends the same way with the same 3 or 4 combatants each stating
their viewpoint, all of which kind of say the same thing in different terms,
and none of them able to acknowledge that the other ones may be right...
either that or one of them who is outright wrong will persist and keep
redirecting the thread until he wins by default. its nothing but a big game
that confuses everyone until they catch on. on a cold winter day it can be
fun, take one of the examples and solve it a different way (i prefer
sinusoidal steady state) and watch them all pull apart the obvious correct
answer with their own methods... it can keep you laughing for weeks!

What about the Poynting Vector and Power Flow Vectors?
What about the 60 Hz "power generation" and "power
distribution" system?

Are you saying that the trailing edge of an ExH wave
is not moving? Are you saying that the ExB power in
the light from Alpha Centauri didn't come from Alpha
Centauri?

buying new ones may be easier.

but if you really want to get them out and if your soil isn't too rocky try soaking them with a hose for an hour or so, just a slow trickle, don't flood the yard. then grab the top with two pipe wrenches so that you can grab one with each hand while bending over the rod and turn the rod both ways... work it back and forth a bit while lifting up, if your back doesn't give out first the rod should slowly pull up. you can also attach a strong rope or cable to it with a couple clamps and pull it out with an old car bumper jack or a long pry bar, but this often takes several lifts, each time moving the clamps down a bit more on the rod.

> Cecil, this is exactly what I've been trying to persuade you of, but always said
> no, there is no short developed. But you must also agree that under this
> condition the current doubles.

Nope, for complete destructive interference, both the E-field and
H-field associated with the two interfering waves collapse to zero.
For the resulting complete constructive interference, the ratio of
the E-field to the H-field equals the characteristic impedance of
the medium.

>>The two corresponding rearward-traveling superposing currents might be:
>>(2a at 180 degrees) superposed with (2a at zero degrees)
>>The superposed sum of the two rearward-traveling currents is zero.
>>This acts like an open where currents go to zero.
>
> Of course, but the voltage doubles.

Nope, again here are the two sets of reflected waves.

#1 100v at zero degrees and 2a at 180 degrees = 200W

#2 100v at 180 degrees and 2a at zero degrees = 200W

Superposing those two reflected waves yields zero volts and
zero amps.

> Well, Cecil, here's where we part company to a degree. Unlike voltage and
> current that can go to zero simultaneously only in the rearward direction, E and
> H fields can never go to zero simultaneously.

For "complete destructive interference" as explained in _Optics_, by
Hecht, the E-field and B-field (H-field) indeed do go to zero
simultaneously. That is what causes a completely dark ring in a
set of interference rings. Of course, a resulting corresponding
complete constructive interference causes the brightest of rings.

> If Steve understands the action of the fields in the EM wave it's hard to

He pretty much ignored current. His power equations are exact copies of
the light irradiance interference equations from optics, but he apparently
didn't realize it until I pointed it out to him.

What are you trying to imply about power generation?

"Power distribution system" is really a misnomer. In the present day
venacular it would be called exactly what it is - an "energy
distribution system".

> Are you saying that the trailing edge of an ExH wave
> is not moving?

I don't recall ever expressing the opinion that traveling waves don't
travel.
However mathematical formulas do not propagate along transmission
lines. Fields do, but there is no such thing as an ExB "field".

I'm not arguing that at all. In a transmission line, destructive
interference causes an energy reflection in which the ratio of
the E-field to H-field is transformed from one characteristic
impedance to another. It's all described on the Melles-Groit
web page. They don't call it an energy reflection but that's
what it is.

Really? It doesn't act like a reflection. There isn't a reflective surface. The amplitude of the "reflection" seems unrelated to any "reflection" coefficient. If it were a reflection, I think it would be much easier to understand - much less controversial. Don't you agree?

Voltage, correct. What other physical parameter(s) of the EM wave
besides voltage and/or current could an in-line meter directly measure?
Why?

> > Instead of posing and then solving a different problem, why not just
> > answer the question I asked?

> I did.

Actually, you didn't. It's a multiple choice question.

How much energy passes a point on that open transmission line in one
second? The choices again are 100 Joules, 200 Joules, or zero Joules.
Please indicate the correct answer from the list of choices.

Well, Cecil, perhaps I don't understand Melles-Griot. However, when an EM wave encounters a short circuit the E field goes to zero, but in its change from normal level to zero, that changing field develops a corresponding H field that adds to its original value, causing it to double--the H field does NOT go to zero. But as it returns to its normal value that change in turn develops a new E field propagating in the opposite direction. From there on the EM field reconstitutes itself with normal E and H fields of equal value, each supporting one half of the propagating energy.

This sequence must also prevail in optics--are you sure you are interpreting your double zero at the correct point in the circles?

URI physics employee invents new antenna technology
Media Contact: Jan Wenzel, 401-874-2116

KINGSTON, R.I. -- June 2, 2004 -- Rob Vincent, an employee in the University of Rhode Island's Physics Department, proves the adage that necessity is the mother of invention.

An amateur radio operator since he was 14, Vincent has always lived in houses situated on small lots. Because he couldn't erect a large antenna on a confined property, he has been continually challenged over the years to find a way to get better reception.

"I was always tinkering in the basement. Thank goodness, my parents were tolerant. I can still remember my poor father driving up our driveway after a hard day's work to see wires wrapped around the house," Vincent recalls.

"The Holy Grail of antenna technology is to create a small antenna with high efficiency and wide bandwidth," explains Vincent. "According to current theory, you have to give up one of the three-size, efficiency, or bandwidth-to achieve any one of the other two."

After decades of experimentation, combined with a 30-year engineering career and Yankee ingenuity, Vincent has invented a revolutionary antenna technology. The distributed loaded monopole antennas are smaller, produce high efficiency, and retain good to excellent bandwidth. And they have multiple applications.

With this technology it will be possible to double, at minimum, the range of walkie-talkies used by police, fire, and other municipal personnel. Naval ships, baby monitors, and portable antennas for military use are other applications. An antenna could be mounted on a chip in a cell phone and be applied to wireless local area networks. Another application deals with radio frequency identification, which is expected someday to replace the

barcode system.

"It could even make the Dick Tracy wrist radio with all the features, such as Internet access, a possibility," Vincent says.

The inventor pursued his quest to build a better antenna in earnest eight years ago when he and his significant other moved into a house situated on a 50-foot by 100-foot lot in Warwick. There was nothing on the commercial market that could fit the lot that would provide the performance Vincent needed to be heard in distant lands and that would be acceptable to his neighbors. All the small antennas being sold were inefficient and lacked bandwidth, which resulted in low performance and high frustration.

Vincent looked at the techniques that were currently used to reduce antenna size and realized something was missing in the way everyone was approaching the problem.

He began to model various combinations into a computer program called MathCad. His first attempt produced a 21 MHz band antenna that was 18 inches high. Normally, antennas for this band are 12 to 24 feet high.

Vincent installed the antenna in his back yard. The legal limit that amateurs can operate is 1,000 watts with the norm being 100 watts. The amateur radio operator experimented with 5 to 10 watts. He reached a station in Chile and made contacts in various European countries. Meanwhile he kept adding power until it reached 100 watts. That's when things suddenly went bad. Walking outside in the backyard, he understood why. The antenna had melted.

After examining the molten matter, Vincent wasn't discouraged. This was only a small model and not designed to handle much power. The part of the antenna that failed proved to be the key to the design. After analyzing the failure, Vincent realized that he was able to transform a lot of current along the antenna with even relatively low power.

"Antennas radiate by setting up large amounts of current flow through various parts of their structure," he says. "The larger the current the more radiation and the better the output of the antenna."

Vincent went back to the drawing board and continued to improve the technology. Relying on his nearly 30 years at Raytheon Co. and at KVH Industries in Middletown R.I which provided him with a diversified background in electronics and electronic systems, Vincent overcame a myriad of problems and succeeded.

He established three test sites for various prototypes. Antennas were placed in Westport, Mass. in a salt marsh, the best ground for transmission and reception. Another set of antennas were placed on rocky ground in Cumberland, R.I., the worst kind of site, and at a Warwick site which is in between the two. The antennas, which resemble flagpoles, worked well at all locations.

Tests confirmed that Vincent has created antennas at one third to one ninth of their full size counterparts. Normally smaller antennas are only 8 to 15 percent efficient. Vincent's antennas achieved 80 to 100 percent efficiency as compared to the larger antennas.

A patent is pending on Vincent's technology. The inventor has made the University of Rhode Island and its Physics Department partners that will benefit from any revenue his invention earns. "The University and its Physics Department has been very supportive and given me time and space to work on this project," says Vincent who was recently presented the 2004 Outstanding Intellectual Property Award by URI's Research Office. "I couldn' t have done this without the University's support. It's only fair that it share in the profits."

3380. Antenna mounting recommendations for flat roof academic building

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-03 22:33:14 UTC
From: Bill Blum <billdotblum@mousepotato.net>
Message-ID: <KGNvc.5074$n65.3079@newssvr33.news.prodigy.com>
Source record: 94035

Hi there--

We've been given permission to mount a few antennas on the roof of one of the buildings at school, with the only caveat being "don't make holes in the roof."

We're looking at some yagis (LPDA, about 12 feet long) for VHF work, and just need to get the things about 10-20 feet above the roof if possible.

Does anybody have any recommendations/tips on how to handle this? At work, I've seen large steel mast mounts than lay flat on a roof to support lightweight/low crosssection antennas... (yes, they're weighted down with concrete blocks.) Where would I find such a beast? Our facility manager has NO idea when these mast mounts wound up on the roof at work.

Thanks.

> >equals 4 - just like the old days. And its not a myth - it really does
work.
> >
> What frequency? What length? What loss did you measure? Was it raining?

freq= 2m band
length = approx 200 ft (up and accross the yard to the top of a TALL TREE)
loss ---- what loss did you measure w/ rg58 (which would have been the
<other> affordable line)
ie: I did not "measure" it - but my signal reports from others were 'much
improved' over the same antenna on the roof.

Raining? - rain, shine, - didn't matter - the run was in free air... I ran
about 10 ft coax out of the house - then switched to twinlead - then back
again near the antenna..
a wives tale - probably so - but I still feel better after eating chicken
soup if I have a cold.
but dogone it - it was fun - I did it - I'm proud of it - and I'll probably
do it again. - It was a good exercise in matching impedences --- I was a new
ham, and wanted to experiment...
I used it because it was light weight and low-loss (per the specs in the
belden catalog) - I don't have the catalog in front of me - but to get the
same <low-loss-ness> I could not afford the hard-line. - and the weight of
that run would have prevented the setup I had in mind.
Plus - I used it as a weather instrument:
if it was wet - rain : it was was swaying - windy, etc.

I understand the limitations of twin-lead and ladder-line, etc - and the
fact that rain and other objects may reduce its effectiveness, etc - but
even if the loss was half as good, it still beat the best coax I could
afford.
Oh - and I used a tree rather than a tower to hold the antenna. - Trees are
kind of old-fashion too, compared with the modern towers.

No, they do not explain the "new" technology. This is the way the CFA and EH got started. Vincent has created a revolutionary antenna technology using Yankee ingenuity. Sorry, being from the South, I don't care for Yankees. More details are needed, but the antenna will be about like the CFA and EH. Build it (when you find out how). It will not work, just like the CFA and EH.

We've always built our own, or rather had the welder do it. Steel tubing, wall thickness determined by loading, weld an H and put the mast in the middle of the cross bar. Lots of good outdoor enamel, and 4 or 8 unopened sacks of ready mix for weights. It conforms to the tubing and roof surface, and won't slide off like cinder blocks have been known to do. After a few months in the weather they are solid blocks with just the right shape. Some of our masts are 20 feet tall, but those are guyed to the tips of the "H".

An antenna that melts with 100W of RF going to it seems to be at odds with
its claim of high efficiency.

Oh come on, he said it's revolutionary! You are being way too judgemental.

The melting probably had nothing to do with losses. I mean, it could
have burst into flames due to corona igniting the revolutionary
materials it was made of, and that's what melted it. Yeah, that's the
ticket.

I was hoping someone else would jump in and answer, but
here goes anyway...

Eric Schumacher, WB6KCN, asked:

> Can anyone give me a brief explanation of the theory
> of operation of a commercial FM broadcast antenna.
> Specifically the Jampro JMPC. Picture at:

http://www.jampro.com/fma/jampjmpc.htm

> It looks to me like a couple of 1/2 wave dipoles
> each folded into V and fed in phase using two gamma
> matches. If this is true I am puzzled by the tap
> point chosen. It seems further along the dipole
> than I am used to seeing, even considering that the
> feed for the dipole is likely 100 ohm. The feed
> must be very inductive.

When the ends of a dipole are folded back, the radiation
resistance decreases and matching schemes have to become
more extreme. The Jampro antenna does not look that
exceptional to me. You're probably right about a certain
amount of reactance accompanying the feedpoint resistance.
This could be tuned out by a matching network hidden in
the feedline/support pipe.

> Polarization is stated as RH circular. How is this controlled?

To my way of thinking, the circular polarization is due to
the horizontal spacing between the horizontal and vertical
dipoles and the phasing of their excitations. If that is
done in a certain way, the far-field radiations from the
vertical and horizontal dipoles will be in time-quadrature
at all azimuthal bearings, the necessary condition for circular
polarization.

If I look at this antenna in a certain way, it looks like
a highly truncated, half-wave section of a bifilar helical
antenna radiating in the radial mode with the two dipoles
simulating the currents flowing in a small segment of such
a structure.

My guess is that getting this antenna to produce good
circular polarization and a good match and uniform
azimuth coverage were the end results of a hell of a lot
of tweaking on the antenna range.

Stand by for a "Revolutionary Antenna Cooling System". Then again, perhaps
we're still thinking too far inside the box. What if this antenna is meant
to radiate HEAT ? Hmmm doesn't do that all that well either - I know
cover the thing in fins like a '60s car...:-)

Of course, it acts like a reflection and of course there is a reflective surface if it is non-glare glass or a point if it is in a transmission line. It is exactly what Walt has dubbed a "virtual short" and it is a short for voltage, but not for current. Walt and my disagreements are really minor.

> The amplitude of the "reflection" seems unrelated to any
> "reflection" coefficient.

It is *exactly* related to the reflection/transmission coefficients. You cannot possibly be ignorant of that fact so you are merely being unethical.

> If it were a reflection, I think it would be
> much easier to understand - much less controversial. Don't you agree?

It *IS* a reflection. Any of your statements to the contrary is just obfuscation (something in which you seem to have a master's degree).

> one half of the propagating energy.

I absolutely agree, Walt, "when an EM wave encounters a short circuit ...".
But when "complete destructive interference" occurs, something else happens.
The E-field goes to zero AND the H-field (B-field) goes to zero at the same
time. If you concentrate on the voltage, it looks like a short. If you
concentrate on the current, it looks like an open. It is both or neither.

Complete destructive interference requires that both fields go to zero
simultaneously and emerge as constructive interference in the opposite
direction obeying the rule that E/H=V/I=Z0. It is an energy reflection
that is also an impedance transformation at an impedance discontinuity.

Let's assume that 100v at zero degrees with a current of 2a at 180 degrees
encounters another wave traveling in the same rearward direction of 100v
at 180 degrees with a current of 2a at zero degrees. These two waves cancel.
The voltage goes to zero AND the current goes to zero. Each wave was associated
with 200 watts. So a total of 400 watts reverses directions. Assuming the
destructive interference occurred in a 50 ohm environment and the resulting
constructive interference occurred in a 300 ohm environment, the reflected
wave would be 346 volts at 1.16 amps. It's pretty simple math.

346*1.16 = 400 watts 346/1.16 = 300 ohms

The above quantities represent the destructive/constructive interference.
These quantities must be added to the other voltages and currents that are
present to obtain the net voltage and net current.

Seems you don't understand the Melles-Groit web page. What it it about
"In the absence of absorption or scatter, the principle of conservation
of energy indicates all "lost" reflected intensity will appear as enhanced
intensity in the transmitted beam."

Richard, can you explain how the above occurs without the energy changing
directions, i.e. being reflected?

I'm too cheap to give up my copper clad steel ground rods! Removal is
really simple using a car jack and a piece of chain. To hook the chain
on the rod, just put a clamp on the rod temporarily. It's actually very
simple and I'm surprised at all the discussion.

Hi Irv,

You must've forgotten all the elaborate discussion from Reggie about how much time the rod needs to become intimate with the surrounding mud (the same mud whose carefully crafted RF recipe remains a secret hidden beneath his apron).

Strangely enough, the topic bears all the mystique of the aging of wine in charcoal casks. Can you imagine the argument turning on if you disturb the bottle - er - ground rod, it could stir up the sediment or make the vintage go corky? Ever try to decant a bottle with a loop of chain and a bumper jack? (Actually I think we tried that with a jug of Sangria along the Russian River north of 'Frisco back in '69.)

> in the roof." ...
Hi Bill,
some hams use an old tyre as the base. They lay it flat on the roof. A
lumber or sheet-metal circle fills the center of the tyre. An approx.
0,5 m (2 ft) long tube is attached vertically in its center. (Do not
forget a small hole for rain water dripping.) The tyre is filled with
concrete then. When the concrete hardens, you have a heavy and sturdy
base for a tube mast. Only the rubber tyre is in contact with the
roof, so no damage should be done. You can roll the tyre on the roof
if you have to move it.
If you need a bigger mounting, use a tyre from a truck or several
smaller tyres. The same tyre base adopted for a rope or wire can be
used for attaching guy wires / ropes.

Hi Thierry.

A simple way to do this is to use a coax as ts the sleeve.

Just cut the coax to a 1/4-wave, connect a 1/4 wire to the inner
conductor at one end of this coax, and feed the other end of the coax
through a choke balun, and there you have it: A simple inexpensive
coax-sleeve antenna.

>
The improvement clearly came from the extra antenna height. If you could keep the extra feedline losses within reasonable limits, you were sure to come out ahead on the deal.

>Raining? - rain, shine, - didn't matter - the run was in free air... I ran
>about 10 ft coax out of the house - then switched to twinlead - then back
>again near the antenna..

Fair enough. If the only other affordable way to get the feedline to the top of that tree would have been 200ft+ of RG-fifty8 (at least 15dB book loss), then direct twin-lead route definitely was the better choice.

>I understand the limitations of twin-lead and ladder-line, etc - and
>the fact that rain and other objects may reduce its effectiveness, etc

You do have the whole picture, Hal, and I respect that.

My problem is with the hams who only know half the story - the claimed advantages. Somehow, it's always the warnings and limitations that get lost... must be "selective fading".

Source record: 94063

Anyone out there have a BWD-65? if so what is the VSWR like at 3.55 MHz?
I will have problems fitting the BWD_90 into my back yard so a BWD_65 would
be better but would like to use it on the VK 80 metre band.
with thanks Andy VK3AS and VK3DTO
replys can come to squires@bigpond.com thanks!

HOw many feet of the rg-59 coax is bwtween the antenna and where you
measured the swr ?
With about 75 to 100 feet of coax you will only see about 3:1 with an open
or shorted coax on the far end.

If you use 5/8 inch garden hose, just slip the hose over the top of the rod and turn on the water. As the flowing water digs around the rod, keep pushing the hose farther down along the rod (and into the ground). After you have about 4 feet of hose into the ground, the rod can be lifted out by hand.

They were around in the '80s and made a line of nice vhf/uhf
transceivers. Long out of biz, as far as I know.

Just wanted to mention that at N6RK in the CA central
valley, we have "cemented hard pan". Like regular hard
pan, only it's water proof. It will stall a D9 Cat if you
try to plow it. We tried all the techniques for rod removal
suggested including soaking it with drip irrigation for
2 weeks. A pipe wrench simply twists the rod, like
a torsion bar. The bottom part doesn't budge. Anyway,
around here, once they're in, they ain't coming out. BTW,
to get it in, it goes in 1/16 of an inch for each hit of a
T-post driver, if you're lucky.

3426. use of wire nuts in antenna construction

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-04 17:16:15 UTC
From: John Shadle <shadle@email.unc.edu>
Message-ID: <Pine.A41.4.44+UNC.0406041312240.44956-100000@login3.isis.unc.edu>
Source record: 93981

Hi. I was thinking about building a 2m five-element quad using the format of KD6GLF (see QST, Jan. 1995) and was wondering about alternative ways to connect the AWG #12 wire to itself on the directors, driven element, and reflectors other than soldering.

I was wondering if any property of the antenna would be changed by using wire nuts instead of soldering the wire together. Has anyone had any experience using wire nuts (on twisted wire) in antenna building?

Thanks for your help,
-john, W4PAH

The fact that transmission lines with high SWRs suffer more
losses than transmission lines with low SWRs proves your
statement to be incorrect. RF energy cannot stand still.
In a transmission line, there are only two possible directions
for energy to travel. There is simply more energy flowing back
and forth in a line with a high SWR than in a flat line. Until
you admit that fact of physics, this discussion cannot progress.

Hi Jim,

Nearly every posting that Cecil pens with his rustic understanding of
Optics suffers from the obvious lack of experience.

There is a certain amount of pretense in this irradiance (an archaic
radiometric term used incorrectly for photometrics in an argument that
calls for luminous flux), much like quoting Iï¿½R and not knowing what
Ohms or Amperes are.

He's lucky there are so very few that appreciate the gaffs of his
unintended humor.

Hi John,

As a splice that is not under tension, should work fine. However, it
does offer the prospect of having to tune slightly differently because
of minimal addition of stray capacitance and inductance - depends on
the size of the nut and the pig-tail it creates. Chances are you
probably would notice the difference because there are so many other
more compelling factors to pay attention to.

As I said earlier, irradiance is proportional to the cross product
of the E-field and B-field. Why do you think we call them fields
if they are not fields?

Exactly how does the irradiance from Alpha Centauri get to
us without propagating? Methinks you are playing word games.

for a weekend like field day it is fine. go much longer and corrosion sets in and can cause all sorts of possible problems. also remember that for a quad those connections may need mechanical strength which you don't get with wire nuts. either solder them or use the brass (or are they bronze?) split bolt clamps.

Everything I write about light/optics comes straight from
Optics, by Hecht. I assume he is more of an expert than
you are and he uses the term "irradiance" for the power
contained in a light beam. Hecht's interference equations
involving irradiance are identical in concept to Dr. Best's
power equations in his QEX article.

Hi Art,

In a crude and shorthand way, yes. This is why your small 160M
vertical dipole is up to 15 to 17dB below performance in comparison to
a full size one. All common legacy for CFAs, EHs, fractals, and the
rest of this ilk that come down the pike.

Cec, you chose the wrong argument! It proves nothing. A 600-ohm open-wire line with high SWR can have a higher loss than even a coaxial line with 1-to-1 SWR.

And loss in the tuner makes the argument even worse.

John,
I haven't used wire nuts, but I have used 1/8 inch cable clamps. I twist the
wires together end to end (Western Union Splice?) and mash the cable clamp
over that. I was concerned about corrosion, but the splices are still good
after 6 years. Possibly the pressure keeps the contact surfaces clean.

Cecil says that a credit card is money, and presumably so is a wire
transfer.
All things are indeed, equal - apparently.

Amazing analogy though - a power debit from one account, a power credit
at the other - without power (or irradiance) having actually traveled
the distance. All owing to the facility that transfers energy.

I'm sorry that you and your friends weren't successful... but that
doesn't prove it can't be done.

Microwave operators regularly use long quads (loop yagis) with 20, 30
and even more elements. Range measurements *prove* that they work, about
the same as conventional yagis of the same boom length, but the loop
elements do have some constructional advantages for the low microwave
bands.

As with any yagi-type antenna, you need to add significant numbers of
extra elements and boom length in order to see a significant increase in
gain. If you do it right, the gain will come.

That was his point, Reg. But it only shows that energy is transferred from the source to the losses at high SWR - not that more energy bounces around. What's Cecil say? I've been seduced by the steady-state, and I don't understand what actually happens? Only people who have opened themselves to the ideals of Reflectology and the Melles-Griot translations, follow the true light.

"Net energy" is still the only energy involved. There are no other choices. The 'other one' you refer to is ficticious, hypothetical, rhetorical, useful to illustrate a point perhaps.

> RF energy cannot stand still.

Time and tide wait for no man.

> In a transmission line, there are only two possible directions
> for energy to travel.

One plus one is two, therefore.....

The truth is even simpler: there is more energy flowing from the source to the losses.

> Until
> you admit that fact of physics, this discussion cannot progress.

If it were a fact of physics we wouldn't be having the discussion. I guess I'll rephrase the question: When the IEEE defines power as energy per unit time, do you think they're talking about a vector quantity?

OK, but for 20m , it means 2x5m of tubing. Not so easy to hang over the
garden.

DO you think that a wire cage qith 3 ou 4 wire could have the same
effect than tubing ?

It doesn't look like reciprocity would work. Is money a credit card
(promise to pay instead of actual payment)?

>All things are indeed, equal - apparently.

Ah yes, appearance, the bane of bandwidth limited perception.

>Amazing analogy though - a power debit from one account, a power credit
>at the other - without power (or irradiance) having actually traveled
>the distance. All owing to the facility that transfers energy.

The power of analogy can be stretched further. Actually money is the
energy (potential for trade) and is exhausted (power dissipated) when
transferred to a debit account. If you tender more money than
required (mismatch) some is returned to you to dissipate later. If
you tender less than required (mismatch) some is expected from you to
make the economic engine go.

If you start trying to substitute, like say explaining in terms of
optics why your bills are chartreuse where most are green - they push
a small hidden button and you are Abu Ghraib bound.

Not to me. It looks like the lindenblad elements are fed IN phase, right?

Differences
JMPC Lindenblad
-two bent half waves -four straight half waves
-Elements in two planes -elements in four planes
-symmetry around the -symmetry around the center
center of the two of the four antennas
elements for 180 for every 90 degrees
degrees of rotation of rotation

similarities
circular polarization
Perhaps fed in phase elements
Weird.

There was an article within there last year, perhaps last Summers antenna
issue which described a "cage" sleeve vertical.

I'm talking about one particular transmission line, Reg.
Given any one particular transmission line, a high SWR
causes more losses than a low SWR. That proves that more
energy is moving in a high SWR environment than in a
low SWR environment. (RF energy cannot stand still.)

Huh?????? Where do the additional losses come from if not from
additional energy? Sounds like you are on to something, Jim -
additional losses without additional energy. You have just
violated the conservation of energy principle. Maybe you can
patent it.

If there's enough sticking up to drive it down about a 1/2" or so that'll loosen it so you jack it out with a bumper jack. If not dig a moat around it to get room. Friction of a small chain wrapped around a few times should hold it, use a small plank if the soil is soft to keep the jack ffrom sinking.. Lubing the moat with water the day before will help.

I think one other factor not factored in (sorry, I just had to do that, it's friday), is that no one has written a good optimizer for loop/quad yagis.

I wonder if one could craft a converter that makes equivalent loops out of regular dipole elements, then you could convert optimized yagis to loops yagis. That assumes a lot, of course, like spacing between the 2 types works the same. Probably won't work at all, but if it's possible to do it, I bet I have the way. Same one I gave to Brian to do scaling in YO. :)

Cecil, at this point I'm not clear what's happening in your above example. Where
and what is the phase reference for these two waves? It appears to me that the
reference phase must be that of the source wave, because the voltage and current
in both rearward traveling waves are 180 degrees out of phase. Educate me on how
the cancellation takes place and how the energy reverses direction.

It seems to me the out of phase voltage yields a short circuit, while the out of
phase current yields an open circuit. How can both exist simultaneously? And

further, what circuit can produce these two waves simultaneously?

In addition, I believe your example has changed the subject. My discourse concerns what occurs to an EM wave when it encounters a short circuit. In this case you're going to have to prove to me that both E and H fields go to zero. IMO it can't happen. The E field collapses to zero while the H field doubles, because the energy in the changing E field merges into the H field. Before the EM wave encountered the short both fields contained the same energy, thus the E-field energy adding to the original H field energy, doubles it, and while that H field was changing it was developing a new E field that launches a new wave in the opposite direction, the reflected wave.

So my argument with you, Cecil, is that I maintain the H field doubles on encountering a short circuit, while you maintain that both E and H fields go to zero. What's your answer to this dilemma?

I can't explain how but I certainly can explain why.

There are only two directions of energy flow available in a transmission
line. Since destructive interference occurs in one direction at a match
point, constructive interference must occur in the other direction. It's
all explained on the Melles-Groit web page and in _Optics_, by Hecht.

J. C. Slater explains how the cancellation takes place.
"The method of eliminating reflections is based on the interference
between waves. Two waves half a wavelength apart are in opposite
phases, and the sum of them, if their amplitudes are numerically
equal, is zero. The fundamental principle behind the elimination of
reflections is then to have each reflected wave canceled by another
wave of equal amplitude and opposite phase."

Note that the above applies to both voltage waves and current waves.
Both voltage and current go to zero during complete destructive interference,
i.e. both E-field and H-field go to zero during complete destructive
interference.

> It seems to me the out of phase voltage yields a short circuit, while the out of
> phase current yields an open circuit. How can both exist simultaneously?

They can't, and that's my argument. It's easy to understand. If the two rearward-
traveling voltages are 180 degrees out of phase then the two rearward-traveling
currents MUST also be 180 degrees out of phase, since the reflected current is
ALWAYS 180 degrees out of phase with the reflected voltage. If one looks only
at the voltages, one will say it's a short-circuit. If one looks only at the
currents, one will say it's an open-circuit.

> And further, what circuit can produce these two waves simultaneously?

According to J. C. Slater (and Reflections II, page 23-9) a match point
produces these two waves simultaneously, two reflected voltages 180 degrees
out of phase and two reflected currents 180 degrees out of phase.

> In addition, I believe your example has changed the subject. My discourse
> concerns what occurs to an EM wave when it encounters a short circuit.

There is no argument about what happens at a short circuit. What I am saying
is that a match point is NOT a short circuit.

> In this
> case you're going to have to prove to me that both E and H fields go to zero.
> IMO it can't happen.

J. C. Slater says that's what happens in the above quote. Voltages 1/2WL apart in time cancel to zero. Currents 1/2WL apart in time cancel to zero.

> So my argument with you, Cecil, is that I maintain the H field doubles on
> encountering a short circuit, while you maintain that both E and H fields go to
> zero. What's your answer to this dilemma?

My argument is that it is NOT a short circuit. It is "complete destructive interference" as explained in _Optics_, by Hecht where both the E-field and B-field go to zero. J. C. Slater says that the two rearward-traveling voltages are 180 degrees out of phase and the two rearward-traveling currents are 180 degrees out of phase. So whatever happens to the voltage also happens to the current, i.e. destructive interference takes both voltage and current to zero.

You know, Walt, just like a wave breaking against the reef. The coral
reflects a wave of water, and a wave of salt, and perhaps a wave of
brine shrimp... If you correspond along these lines long enough, you
may rummage up a chowder from Cecil, but I wouldn't expect
Chateï¿½ubriand.

Some of the surge protectors have RF isolation, but most of the
low-cost ones do not. Winding the cords around a ferrite rod might
help, but I'd try connecting your antenna tuner to a good ground, then
follow the advice of someone else here - use only enough power to
maintain communications. Balanced feeder to the antenna line will
probably help also if that's possible in your situation.

If you value radio, this may be the last and only chance to have your voice heard to stop BPL from destroying your hobby. The FCC has extended the comment period for BPL.

It is VERY simple to file a FCC comment. Click the link below and enter

03-104

in box #1 (proceeding number) and fill in the blanks. The simplest way to comment is to type your comment into the box on the bottom of the form.

http://gullfoss2.fcc.gov/prod/ecfs/upload_v2.cgi

If you can't think of any thing to type or wish to make this as painless as possible, you can cut-n-paste the comment I typed below.

/******************************/

In Writing, I wish to persuade the FCC from allowing BPL to be implemented. The destruction or at the least, deterioration of the shortwave bands is not only a violation of ITU laws that protect international broadcasters from interference and jamming, it will be destroying many people's life hobby. Amateur radio will be reduced to users with high-power amplifiers and large antennas. Emergency communications will be hindered to levels directly responsible for the loss of life.

There are many technologies that make BPL unnecessary. BPL will never be able to carry the high bandwidth demands for mass distribution of video much less the up-and-coming HDTV.

Please do not destroy the foundation of radio communication for a unneeded technology that is only a band-aid and hindrance to the advancement of broadband technology.

>loops yagis.

The practical advantages of loop yagis lie in their element construction, which is a circle rolled from flat strip. Unfortunately, that is a very difficult shape to model with any software I'm aware of.

>That assumes a lot, of course, like spacing between the 2 types works
>the same.

Which it doesn't, because parallel-spaced loops are very obviously different from parallel-spaced rods, and are going to interact in a different way. The general rules for building yagis are the same - progressively shorter loop lengths along the boom; progressively increase the spacing until you reach a certain limit, and then keep it constant - but the details are definitely going to be different. And it's those small details that make the difference between a good, average or poor yagi.

>Probably won't work at all, but if it's possible to do it, I bet I have
>the way. Same one I gave to Brian to do scaling in YO. :)
>
It would certainly be very difficult, but I doubt if it will ever be done. Existing loop yagi designs are already quite close to the theoretical optimum for the boom-length, so the limited rewards wouldn't justify the effort.

Cecil, your reference below to Chapter 23 in Reflections has re-oriented me and I'm now on your page. This is the case of a 1/4wl matching transformer. I didn't recognize my own writing. Sorry.

>J. C. Slater explains how the cancellation takes place.
>"The method of eliminating reflections is based on the interference
>between waves. Two waves half a wavelength apart are in opposite
>phases, and the sum of them, if their amplitudes are numerically
>equal, is zero. The fundamental principle behind the elimination of
>reflections is then to have each reflected wave canceled by another
>wave of equal amplitude and opposite phase."

Yes, Cecil, this quote is my Ref 35, which I used to support this concept in my QST article in Oct 1974, so I am well familiar with it. And yes, you are correct in that the waves reflected from points A and B in Fig 6 are in the phase you state.

>Note that the above applies to both voltage waves and current waves.
>Both voltage and current go to zero during complete destructive interference,
>i.e. both E-field and H-field go to zero during complete destructive
>interference.

But Cecil, take another look at Fig 6 on page 23-5 to note that those two waves arrive 180 out of phase at point A, which means only that the E and H fields cancel in the rearward direction only, resulting in a Zo match to the source. But what's important (and I inadvertantly omitted this fact in the book, which will be corrected in III) is that when the waves reflected from B reach A they find a discontinuity at A of an open-circuit type condition, because the line Zo now goes from low to high (in the rearward direction). Thus when the waves reflected at B arrive at A the voltage which is already at 360 (0) degrees does not change phase, but the current which is at 180 degrees on arrival changes by 180 due to the open circuit at A to rearward traveling waves. Thus the current is now also at 0 degrees. With both voltage and current at 0 degrees relative to the source, all the power in the waves reflected at B are re-reflected at A and add to the source power.

Consequently, Cecil, both the E and H fields go to zero only in rearward direction at the match point, which is necessary for no reflections to travel rearward of the match point, but the H field goes to zero only temporarily while the E field is doubled temporarily, as they should when encountering an open circuit as they do on arriving at A.

>> It seems to me the out of phase voltage yields a short circuit, while the out of
>> phase current yields an open circuit. How can both exist simultaneously?

I've answered my own dumb question here.

>They can't, and that's my argument. It's easy to understand. If the two rearward-
>traveling voltages are 180 degrees out of phase then the two rearward-traveling
>currents MUST also be 180 degrees out of phase, since the reflected current is
>ALWAYS 180 degrees out of phase with the reflected voltage. If one looks only
>at the voltages, one will say it's a short-circuit. If one looks only at the
>currents, one will say it's an open-circuit.

I think I've addressed this paragraph above.

>> And further, what circuit can produce these two waves simultaneously?

As I embarrassingy discovered it's the 1/4wl transformer--dumb me.

>According to J. C. Slater (and Reflections II, page 23-9) a match point
>produces these two waves simultaneously, two reflected voltages 180 degrees
>out of phase and two reflected currents 180 degrees out of phase.
>
>> In addition, I believe your example has changed the subject. My discourse
>> concerns what occurs to an EM wave when it encounters a short circuit.

I was confused here, Cecil, because you did change the subject from discussing what happens to the E and H fields when encountering a short to the 1/4wl transformer example without my catching on to the change. As I said, dumb me.

>There is no argument about what happens at a short circuit. What I am saying
>is that a match point is NOT a short circuit.

In this case the match point at A is an open circuit.

>> In this
>> case you're going to have to prove to me that both E and H fields go to zero.
>> IMO it can't happen.
>
>J. C. Slater says that's what happens in the above quote. Voltages 1/2WL apart
>in time cancel to zero. Currents 1/2WL apart in time cancel to zero.

Yep, but only in the rearward direction.

>> So my argument with you, Cecil, is that I maintain the H field doubles on
>> encountering a short circuit, while you maintain that both E and H fields go to
>> zero. What's your answer to this dilemma?

We've answered this.

>My argument is that it is NOT a short circuit. It is "complete destructive
>interference" as explained in _Optics_, by Hecht where both the E-field and
>B-field go to zero. J. C. Slater says that the two rearward-traveling voltages
>are 180 degrees out of phase and the two rearward-traveling currents are 180
>degrees out of phase. So whatever happens to the voltage also happens to the
>current, i.e. destructive interference takes both voltage and current to zero.

I'll not argue with the way Hecht describes the phenomena.

G'nite, Cecil, it's 3 :20 AM and I've got to go back to bed.

3481. VHF yagi element diameter

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-05 10:02:52 UTC
From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <2idk1mFm05hoU1@uni-berlin.de>
Source record: 93936

I've got a design from Wes Stewart (see "Wideband VHF Yagi - Do I have to use a folded dipole configuration?" below) for a 6 element yagi covering 156-162 Mhz. I'm not sure what is, I mean NBS, OWA.-whatever. (Wes, I'd like to know if possible because then I know what I'm dealing with).

Anyway, DE is 5/16" and parasitic elements are 3/16" in this design.

Now not being an antenna buff I have, regarding the element diameters, the following thoughts arise:

1 Better not think about altering any of the element diameters. Advantages: Does not run risk of altering design performance. Disadvantages: If I alter diameters then maybe performance will suffer or I'll have to try to engage in a bit of designing myself to ensure performance does not suffer from any changes.Hey I'm not a designer.

2 Stick with diameters because the element diameters given seem to me to make for a lighter antenna with reduced windload. Why increase element diameters (if you don't feel you have to) if there is no performance advantage, all you are doing is creating a bulkier antenna.

3 Alter element diameter(s) because of the limitations imposed by the materials you can get your hands on. For instance let's say I can buy a commercial dipole center peice that takes 1/2" tube. So, the reasoning is alter DE to 1/2", make any adjustments to maintain performance. And what if you could buy commercial fixings that allow you to fix 3/8" tube, you might then decide to substiutute 3/8" tube for the 3/16" parasitic elements.

As you can see, all these things go thru my mind after being presented with a design, and I get a bit flustered.

You might say that the conserative guy, afraid to risk anything just sticks with the original elemment dimentions no matter what.

The give-it-a-go guy says, don't be afraid, if you feel you want to use 1/2" for DE, and perhaps 3/8" for the parasiticvs, alter that in the 4nec2 programme and see what happens. Or is that going to lead to disaster! The changes being too great.

One thing though, I suppose after makling alterations and before construction, one could pass the new design through the hands of antenna buffs. Dead simple to email the NEC file.

One time most constructors would just be presented with a design and they would stick to it no matter what. Nowadays with these antenna programs people who know little (like me) can seek to mess with the design if for instance one has some tubing to hand that is not the same diameter as in the

design. Perhaps that can be gotten away with. Maybe.

I think there is something to be said for 2. Might mean items are not available off the shelf though.

> I think there is something to be said for 2. Might mean items are not
> available off the shelf though.

Actually the only issue is the dipole center peice. Getting 3/16"and 5/16"
tubing is no big problem, (although a lot of stockists just have 3/8").

5/16" will fit with sleeving in a dipole center peice meant for 1/2"tube.

I bet I could substitute 5/16" with 3/8" for DE in the design with very
little efect.

That leaves me to mount 3/8" tube in a dipole center peice meant to take
1/2". Simple, sleeving should do.

And then you think, ah, just use 1/2" tubing for DE. Again that won't make
much difference.

3483. Lightweight yagi antennas as a design philosphy

Newsgroup: rec.radio.amateur.antenna

Is anyone engaged is a design philosophy that seeks the design of VHF yagi's with the smallest acceptable diameter of elements?

What you are trying to do is to design lighweight VHF yagis, you are seeking how small you can go with element diameters before performance begins to suffer.

3484. Re: VHF yagi element diameter

From G3SEK site:

IMPORTANT WARNING!
If you are copying an existing Yagi design, you must copy:

all the element lengths
all the element diameters
the element mounting method - why?
That means: copy EXACTLY! If you change any of these important details, you are building a new design!

Gosh, just what m I getting myself into here. All I have is an NEC file for a 156-162 Mhz yagi.That's a long way from having a design is it not.

3485. Something for someone to do.

I don't know whether I've got the know-how or the time to design a homebrew VHF yagi for the marine band.

So, is anyone out there interested in providing a service to all marine band DXers/eavesdroppers of designing and producing *full constructional notes* on a range of marine antennas, and then putting the designs up on a website.

All antennas shall principally be for reception.

All antennas should be described as covering 156-162Mhz.

As far as the yagis are concerned, they should range from 2 to 6 elements.

All yagis shall have 4mm (or 3/16") diameter parasitic elements.

All parasitic elements shall be secured to boom by nylon rivets as per G3SEK's notes at:
http://www.ifwtech.co.uk/g3sek/diy-yagi/#Construction

All booms shall consist of either 20mm or 15mm square tubing.

The DE for all yagis shall be 8mm (or 5/16").

The DE for all yagis shall be a regular hertz dipole.

There shall be some kind of balun.

Please, please!

I think this is reasonable. It will keep the antenna lightweight. Why have
bigger if you don't have to.

> The DE for all yagis shall be 8mm (or 5/16").

Possibly this could be 3/8" because this size might generally more easily
available.

> The DE for all yagis shall be a regular hertz dipole.

Why have a folded dipole if you don't have to.

How are you going to mount DE? Are there any commercially availble dipole
centers that take 5/16" or 3/8" tube? Will you have to homebrew the dipole
center peice?

(In UK I can obtain commercial dipole centers that hold 1/2". I've not
sourced any others that take 5/16" or 3/8").

Here's the text I entered - feel free to cut / paste / modify, etc.

Dear Commissioners, I wish to express my opposition to Broadband Over Power Line (BPL).

My opposition is based on the interference to the Amateur Radio service and to those listening to shortwave radio.

The Amateur Radio service was a valuable service on 9/11, providing communications backup and helping survivors contact loved ones. Given the current terrorist threat we now face, I believe that it is unreasonable to hamper this valuable - and free - resource with a known source of interference.

Further, it is simply unnecessary. While I'm sure that the power companies are looking for a new profit center, that is insufficient reason to allow them to run roughshod over others who don't have the enormous budgets for political lobbyists. There are other alternatives available for broadband that don't interfere with other services, including cable, DSL and satellites services such as DirectWay.

Thanks you for considering my petition.

Charlie, KS1C

If I was going to put up an antenna like that, I would look for a used
CushCraft 2m 7 element antenna, and cut it down. I once bought one for
U$7.00. Several years ago QST had an article on making a VHF TV antenna work
on 2M; Changing that to 156-162 instead should be simple.

This would probably be the start of your 6 element design:

Parasitic elements 4mm dia rod , DE 8mm or 5/16" tube.

```
------------------|------------------- R 37.106"
| ^ 0.000"
------------------|------------------ DE 36.772"
| ^ 9.275"
------------------|------------------ D1 34.154"
| ^ 12.250"
------------------|------------------ D2 33.34"
| ^ 23.800"
------------------|------------------ D3 33.34"
| ^ 34.213"
------------------|------------------ D4 32.58"
^ 47.211"
```

IOW:
X Y Z Dia"

REF End 1 0.000 -18.553 0.000 0.187
End2 0.000 18.553 0.000

DE End1 9.275 -18.368 0.000 0.312
End2 9.275 18.368 0.000

DIR1 End1 12.250 -17.077 0.000 0.187
End2 12.250 17.077 0.000

DIR2 End1 23.800 -16.672 0.000 0.187
End2 23.800 16.672 0.000

DIR3 End1 34.213 -16.672 0.000 0.187
End2 34.213 16.672 0.000

DIR4 End1 47.211 -16.229 0.000 0.187
End2 47.211 16.229 0.000

Boom 15mm square, 50" long.

Parasitic elements slotted through boom with nylon rivets system.

DE using commercial dipole center peice.

DE hertz dipole with some kind of balun arrangement.

Potential problem?: Parasitics slot through boom because they are held in place (say) by the nylon rivets system, DE will *not* pass through boom but above it. Will that make a difference?

As you see I have some dimensions given me, but I have no skill to take these dimensions (assumimng I stick with them) as a starting point and produce an actual constructional design.

Richard,
I think if it is heavy enough to physically support itself, it will be electrically OK. This turns out to be about 1/4 inch (6 mm) tubing at 50 MHz, and 1/8 inch (3mm) hard aluminum rod at 144 MHz and above.

That quote is from my 'VHF/UHF Long Yagi Workshop' page - one click from
the home-page link below.

I've just updated that page, and there is now more information about
changing element diameters and mounting methods - including a small
MS-DOS program to do the boring calculations.

(I'm supposed to be painting window-frames, but this is so much more
interesting...)

use a car jack to remove the rod or a holmes wrecker, i have used a bumper jack to pull out rods before , all you do is place the jack under the head of the ground rod and start jacking it up out of the ground and then when the jack runs out of lift simply just lower the jack head down lower and start over and it will lift 4ft at a time.... and use lots of water on the ground rod... it will kinda lubricate the rod.

You can still buy the old Flexa-Yagis that use very thin, springy
elements made from stainless steel.

Skin losses in the stainless steel cost about 1dB at 144MHz, but no
lower-loss material has the mechanical strength to survive the loading
from ice or optimistic birds.

Very thin elements are also a serious danger to eyes and, er, other body
parts.

What a disservice to the great name of Tesla.
Using loading coild to shorten the antenna and slap Tesla name on it to make "waves" in Antennex (BS) "magazine"?
Yea spherical top is universe "invention". I got the copper toilet bowl float on the top of my vertical to prevent corona and add some top loading and broadbanding.
Brace yourself for more "inventions" to come as we get flooded with more of un-knowledgeable hams.
Hey, maybe there is a room to sell wunderantennas to idiots?
I have 50 ohm DC to light 100% efficient, fits in a pocket miniature antenna for $100. (Secret? it is made by Ohmite) There is another one produced by GE or Phillips in China and it even provides light when power applied to it. You can use it as a lightbulb too.
I will share my profits with US gubermint.

Thanks. Of course over the years I'm used to seeing commercial TV and FM antennas which tend to use 3/8" and greater for elements and because just recently I've been comimg across designs using 4mm tubing it seems odd to me. As if there's just got to be some big losses or compromises on using say 4mm dia rod. But I now see that quite standard of course to use 3 and 4mm elements for high band VHFyagis. All is rather new to me. I should be seeing 4mm rod as the norm for a VHFhigh band yagi.

Actually, the figure for the parasitics were given as 0.187" dia. that's
about 4.75mm or nearer 5mm than 4mm.

This is admirable.

Let me understand:

You mean that it takes weeks of constant work and a deep knowledge of antenna theory and design to take an off-the-shelf NEC file (which you can buy for a few bucks, and probably many are freely available) - to end up with a half decent antenna?

If that is the case, then of course my expectations may be unrealistic.

But I was thinking that for someone who knew what they were doing, taking an NEC file as a starting point and then applying adjustments to take into account the actual construction details would be a few hours work. Because antenna programs do all the calculations. You just need to know what you are doing.

I would not want anyone spending much time on something, of course. I just thought for someone who knew what they were doing it would a be a doddle. Heck, the real design work has been done already, it's just a matter of a few small adjustments. So I thought.

But if that is not the case, I stand corrected.

And if so, so I'd have no option but to do everything myself. Because that would practically be unavoidable. I never thought this was the case.

3504. FS: Millen antenna tuner

Have a James Millen antenna tuner, 92201. This is the 300 watt model but will take considerably more. 10-80 meters, panel is excellent, and included is the rare (yes, it is rare, hi) original owner's manual. Tuner can also be used between a solid state rig and a linear if the linear doesn't have an input circuit. $105 plus shipping, continental US only, please.

73s,

Evan

I bought some "models" from Mr Cebik.

This is what he says in his notes:

" Although many of the designs may be directly built from the models in this collection, the models themselves are for study purposes. Perfecting the design to a level that permits construction of an antenna that is both electrically and mechanically sound is your responsibility.

L. B. Cebik, W4RNL"

This is my problem and what I was asking for. I can mess around with the models quite freely, but perfecting the design to a level that is both electrically and mechanically sound is right now beyond me. What you are saying is that this task is such a huge one and requires great skill. Not easy then for your regular Joe ham to do much with the models in a practical way. He/she has to become something of an antenna buff for that to transpire. And because the task is so demanding, no antenna buff would ever consider producing an actual contstruction design for anyone, apart from him/herself maybe. And then he/she might condescend to allow others to copy his/her design.

The performance that suffers (afaik) from smaller antenna elements is a
small lowering of the 'bandwidth' of the antenna, and maybe a small change
in the 1:1 swr tuning point. Mind you I'm not an expert on Yagi antennas

I built, for a 'start from scratch' foxhunt, a 3 element yagi on 2m (~146
mhz) out of magnet wire glued onto a piece of poster board. I used standard
numbers and it worked fine. The hardest part was soldering wire thinner than
my hair to the coax and anchoring the coax to the poster board so it would
get pulled off.
I won the hunt over all the 'body shielded ht' guys, even taking 10min to
build my antenna...

Later that week I used it to call into a net on a local repeater, so it
handled 15 watts without anything melting.

Much more critical on a Yagi are element spacings (directivity and
Front:back ratios) and lengths (resonant frequency).

Some of the variation in the size of tubing seems to depend on the quality
of the tubing used. Any ham antenna I have seen uses seamless fairly hard
alloy, whereas some TV antennas use a larger diameter rolled (if that is the
right term) tubing of very thin material.

Yes, and that is exactly my point. EXACTLY the same thing happens to the E-fields and H-fields. That means exactly the same thing that happens to the rearward-traveling voltages also happens to the rearward-traveling currents. Two equal-magnitude/opposite-phase voltages cancel. Two equal-magnitude/opposite-phase currents cancel. That doesn't happen at either an open or a short. If one looks at just the voltages, it looks like a short. If one looks at just the currents, it looks like an open.

> With both voltage and current at 0 degrees relative to
> the source, all the power in the waves reflected at B are re-reflected at A and
> add to the source power.

Reflected waves ALWAYS have the voltage and current 180 degrees out of phase. "With both voltage and current at 0 degrees" implies a forward wave which is the *EFFECT* of re-reflection, i.e. after re-reflection. The rearward-traveling voltage and current CANNOT be in phase before the re-reflection. After the re-reflection, they are no longer rearward-traveling so they are in-phase and forward-traveling. It's a cause and effect thing.

1. Proper adjustment of the tuner/stub/quarter-wave-transformer CAUSES all voltages and currents at the perfect match point to be in-phase or 180 degrees out of phase.

2. Destructive interference between two rearward-traveling waves of equal magnitudes and opposite phases causes the E-field voltage and H-field current to go to zero simultaneously, i.e. the E-fields superpose to zero in the rearward direction and the H-fields superpose to zero in the rearward direction. EXACTLY the same thing happens to the H-fields as happens to the E-fields in the rearward direction. Neither a short nor an open acts like that.

"... reflected wavefronts INTERFERE DESTRUCTIVELY, and overall reflected intensity is a minimum. If the two reflections are of equal amplitude, then this amplitude (and hence intensity) minimum will be ZERO." From the Melles-Groit web page.

3. "... the principle of conservation of energy indicates all "lost" reflected intensity will appear as enhanced intensity in the transmitted beam." Quoted from the Melles Groit web page. They don't say how but they do say why. In a perfectly matched system, all rearward-traveling energy changes direction at the match point and joins the forward wave as constructive interference. That constructive interference energy is equal in magnitude to the energy involved in the destructive interference event. It's a simple conservation of energy

process.

>>There is no argument about what happens at a short circuit. What I am saying
>>is that a match point is NOT a short circuit.
>
> In this case the match point at A is an open circuit.

Destructive interference causes the rearward-traveling voltage to go to zero.
Voltage doesn't go to zero at an open circuit. Exactly the same thing happens
to the rearward-traveling voltages and rearward-traveling currents. Voltage
goes to zero at a short-circuit. Current goes to zero at an open circuit. A
match point causes both to go to zero in the rearward direction. That means
the voltage sees a short-circuit looking rearward and the current sees an
open-circuit looking rearward.

"Consequently, all corresponding voltage and current phasors are 180 degrees
out of phase at the matching point. ... With equal magnitudes and opposite
phase at the (matching) point, the sum of the two waves is zero." _Reflections_II_,
page 23-9. This is true for both step-up or step-down impedance discontinuities.
At a perfectly matched point, the two rearward-traveling voltages are ALWAYS of
equal magnitude and opposite phase. The two rearward-traveling currents are
ALWAYS of equal magnitude and opposite phase. That's the only way complete
destructive interference of rearward-traveling waves can occur.

>>J. C. Slater says that's what happens in the above quote. Voltages 1/2WL apart
>>in time cancel to zero. Currents 1/2WL apart in time cancel to zero.
>
> Yep, but only in the rearward direction.

The rearward direction is what we are talking about. The point is that EXACTLY
the same thing happens to the two rearward-traveling current waves as happens
to the two rearward-traveling voltage waves. A short-circuit doesn't affect
voltages and currents in the same way. An open-circuit doesn't affect
voltages and currents in the same way. A match point affects the rearward-
traveling voltages and rearward-traveling currents in EXACTLY the same way.
The re-reflection at a match point is a conservation of energy reflection where
the rearward destructive interference energy supplies energy to constructive
interference in the opposite direction. For light, the equation are:

Destructive Interference Irradiance = I1 + I2 - 2{SQRT[(I1)(I2)]} (9.16)

Constructive Interference Irradiance = I1 + I2 + 2{SQRT[(I1)(I2)]} (9.15)

Optics, by Hecht, fourth edition, page 388

Note the similarities to equations 13 and 15 in Dr. Best's QEX article,
Part 3.

PFtotal = P1 + P2 - 2{SQRT[(P1)(P2)]} (Eq 15)

PFtotal = P1 + P2 + 2{SQRT[(P1)(P2)]} (Eq 13)

Too bad he didn't label them as Hecht did, as "total destructive interference"
and "total constructive interference" equations.

I'm going to look at Enzec help files, I suspect I can do my own work
starting with a model. Producing full constructional notes should not be
difficult.

>become something of an antenna buff for that to transpire.

A few years ago, if any amateur got involved in the esoteric art of antenna modelling, it was because he or she was *already* an advanced antenna buff, with lots of hands-on experience of making antennas work.

After learning about modelling, with all its tricks and traps, the next challenge was to learn how to translate the models back into workable hardware. But at least that was building a bridge between two solid foundations.

Now, it's becoming the other way around - the modelling is more accessible than the hands-on experience. Without that practical experience, translating a model into reality is like building a bridge to nowhere.

It isn't "something for someone [else] to do." Someone else can run models for you, but only the person with the hardware in their hands can work out how to build the real thing.

However, about the worst you can do is cut the elements to the wrong lengths. The program on my website (see earlier posting) will help, and you should also read all three of the links from that same page.

If you come back with a question more like: "I've tried to work out how to do this. Here are the model dimensions, here are my cutting dimensions, and here's why. Does this look reasonable?" then I'm sure you'll get a lot more help.

(Coffee mug's empty... back to the window-frames.)

I designed and built the monitoring system for the plant. to directly
measure "resistivity" in ohms per cubic centimeter. As far as I know,
they are still using the same monitor over 30 years later.

>According to an article by N6CA (which was in the ARRL Handbooks for

You actually either measure or convert to ohms per cubic centimeter.
Typically the water is changed out over time, rather than letting the
resistivity drop and then change. They might dump a hundred gallons
a day, a week or what ever and replace with fresh.

Of course there was the time some one dumped a small salt shaker in
the drain. A spoon full of salt is enough to render many thousands of
gallons out of spec. Actually it shut down that part of the
operation.

==========

Why?

What's the percentage current unbalance on the balanced line when there's a
450-ohm to 50-ohm, balanced to unbalanced junction without a balun?

What percentage current unbalance does a typical choke balun reduce
unbalance to -

- - - - with a receiving antenna ?

- - - - with a transmitting antenna ?

if there's any difference.

> currents.

In my class in secondary school counseling, I learned a technique that might be helpful here. It's called, "Be the thing." Whatever it is that you are trying to understand, mentally become that thing. In other words, assume that you are the reflected current to find out what you would experience. Obviously, it is just a mental exercise, but one that I have found quite useful throughout the years.

First, assume that you are the reflected voltage from a mismatched load. What do you encounter back at the match point? You encounter another reflected voltage with equal magnitude and opposite phase traveling in the same rearward direction. What happens to you? Your momentum in the rearward direction is reversed and your energy starts flowing toward the load. As a reflected voltage, based on your necessarily limited knowledge, you assume that you must have encountered a virtual short circuit.

Second, assume that you are the reflected current from a mismatched load. What do you encounter back at the match point? You encounter another reflected current with equal magnitude and opposite phase traveling in the same rearward direction. What happens to you? Your momentum in the rearward direction is reversed and your energy starts flowing toward the load. As a reflected current, based on your necessarily limited knowledge, you assume that you must have encountered a virtual open circuit.

There exists an apparent contradiction. A match point cannot simultaneously be a virtual short and a virtual open. How is the apparent contradiction resolved? Is there anything else in physics that can cause a total reflection of energy besides a short, open, or pure reactance? The answer is, "yes", and it happens all the time in the field of optics. In a system with only two directions of energy travel available, total destructive interference in one direction has to result in total constructive interference in the other direction. That's the way perfect non-glare thin-film coated glass works in the presence of a coherent single-frequency laser beam.

You didn't give enough information for anyone to provide a valid answer,
Reg. What is the impedance from the junction looking back toward system
ground? If it is three ohms, a balun is necessary. If it is 300 ohms,
you can probably get by without a balun.

OK, so it's 3 ohms. Wot's the percentage unbalance ?
Just a number is required.

If it's 300 ohms. Wot's the percentage unbalance ?
Just another number is required.

What are the odds on you providing answers ?

>the presence of a coherent single-frequency laser beam.

Yes, Cecil, I understand. However I don't particularly like the notion of saying both fields go to zero, or both fields go to zero in the rearward direction. Confusing. Remember, weeks ago I swore that both fields could never go to zero simultaneously? The reason I disagreed with you is that you didn't mention the 'direction'. The reason I dislike hearing that both fields go to zero is that it's really not true. Like I've said many times, on encountering a short,circuit voltage and the E field go to zero and the current and H field doubles AND REVERSES DIRECTION. To me, Reversing direction is more meaningful and less confusing than both going to zero, and it still says there is no energy propagating rearward of the match point.

Going now to the cancellation process when the voltages and currents of both waves are mutually out of phase. You say that voltages 180 out yields a short (agreed) and that currents 180 out yields an open. Sounds good, and I mistakenly agreed a coupla days ago. But I don' think so. I believe voltage 180 out defines a short--period. Look at it this way. Take a zip cord and put male plugs on both ends. Plug one end into an outlet, say the top one, and then plug the other end into the bottom outlet with the polarities reversed. With respect to voltage we have a 'circuit breaker' short circuit, because the voltages entering the zip cord at each end were 180 out. But so were the currents initially. Then why the short circuit current flow? Certainly not because the circuit is open to current.

Another scenario with the same initial conditions and results: Take two identical generators delivering the same level of harmonically related output voltages. Connect their terminals in phase.Voltages in phase--currents in phase. Result? No current flow. Why? Zero voltage differential. Open circuit to voltage--open circuit to current.

Now reconnect their terminals in the opposite manner. Voltages 180 out--currents 180 out. Do we have current flow? You bet--dead short! Because current results from voltage, if voltages are 180 out of phase we have a short to both voltage and curent. No open circuit to current.

Cecil, I hope we're both still on the same page on this one;

Walt

But Walt, that's exactly what happens when total destructive interference
occurs as explained by J. C. Slater in _Microwave_Transmission_.

> I believe voltage 180 out defines a short--period.

That same belief is what got Dr. Best into trouble. He never considered
what happens to the reflected current waves. In a sense, your and his
disagreements are because you both made the same conceptual mistake and
arrived at different conclusions because of that common mistake. If you
and he had not made that shared mistake, you both would have arrived at
the same conclusions.

This is the problem with trying to use circuit analysis to replace network analysis.
Put the two sources at the two ends of a transmission line and please reconsider
the outcome. Equip the two sources with circulators and dummy loads so the outcome
cannot be in doubt.

>

>Too bad he didn't label them as Hecht did, as "total destructive interference"
>and "total constructive interference" equations.

Sorry, Cecil, in spite of their similarity with Hecht's, these equations are totally invalid. Steve derived them from his Eq 9, which is also totally invalid for use with reflected power. This equation is correct and valid when there are two separate and individual sources. But here there is only one source, the transceiver. When connecting two batteries in series Eq 9 works, because there is enough energy there to support the additional current demanded with the increased voltage. But not when the transceiver is the sole source of power.

With the transmission line system Steve's voltage V2 comes from the same source as V1. The problem is that when the total forward power resulting from the addition of reflected power and source power the total forward power is never absorbed in the load, the power resulting from the reflection is subtracted from the total power. This limitation does not occur when there are two separate sources to maintain the increased current.

Because Steve used Eq 9 in an invalid way to derive Eqs 10 through 15, all of these derived equations are also invalid. Try Eq 13 for example. It says 75 w plus 8.33 w = 133.33 w, as you well know. This is absurd!

In addition, because the powers don't add up correctly using V1 and V2 at zero phase relationship, he concocted the ruse that they must add vectorially, and he goes through several values of phase relationships to show what the forward power would be with the various phases. This is poppycock, because the phase relationship between the source (V1) and re-reflected voltage (V2) is ALWAYS ZERO on lossless lines.

His initial problem is that he misinterpreted Eq 6 in Part 1 to yield the forward voltage Vfwd, where it actually yields the voltage E of the standing wave at any point on the line, where the point on the line is determined by the 'L' term in the exponents on the right-hand side of the equation. In other words, the summation of terms on the right-hand side of his Eq 6 does not equal forward voltage Vfwd, as it indicates incorrectly, but instead equals the voltage of the standing wave.

In addition to other errors, the entire right-hand column of page 46 is invalid.

Pore deprived thing.

You study some of the mountain of illustrated artcles in the ham
literature which show how others have sucessfully put VHF Yagis
together to get an education on the various "basement engineering"
practical mechanicals they came up with.

You run the model based on the materials you have available and the construction scheme you have chosen.

You build it. You test it. You tweak it. You put it up again and go SWLing on
162 Mhz.

No, you don't have to be an "antenna buff" to do any of it these days.

But if you build your own you do have to get off your butt and put a bit of your own mental effort into the matter. Don't hold your breath while hoping that somebody around here will save you from the butt-lift maneuver just because you don't wanna do it yourself.

Cecil, how do you figure I made a mistake in this issue? I have always considered voltage 180 out as a short. And my writings show voltage at 180 as a short, as stated on page 23-9. I agree that the opposite phases of both voltage and current in that discussion resulted in the cancelation of reflected power traveling in the 225-ohm section of line. And during the last day or two I leaned toward thinking the out of phase current implied an open circuit. But you can see from my words above that voltage rules--when the voltages are 180 out of phase it defines a short circuit. My zip cord example is evidence to that. Consequently, I don't agree that Steve and I made the same mistake. My writings delivered the correct mathematical answers--Steve's does not. The mistake I made on page 23-9 is in overlooking that it is the effective open circuit condition seen looking in the rearward direction by the reflected waves at point A is what gave both the voltage and current waves the reversal and phase change to zero relative to the source waves.

Pound 'em down (say 4-6" below surface, then backfill the hole) and buy new ones.

They're cheap and if they've been in the ground any time they'll 1) probably be hard as hell to pull and 2) probably have corroded to the point where new ones would be well worth the $.

Here's my letter, for what its worth:

I am writing to ask you not to allow the implementation of BPL
(Broadband over Power Lines) in our nation's communities.

I rely on shortwave radio as a source of entertainment, world news and
cultural information. I listen to low & high-power broadcasts from the
world over. Reliable reception is already a challenge due to the
interference caused by the deplorable state of our nation's power
lines. I have had to send several complaints to my local power company
due to electrical power pole arcing that interferes with my shortwave
radio. Adding broadband data to these already unreliable power lines
would render a bad situation worse. In my experience, power companies
have little regard for complaints regarding radio interference, and
are slow to respond, if at all. I consider it irresponsible to entrust
BPL technology to power companies that already have an indifferent,
monopolistic attitude towards customer service.
Power companies are also overwhelmed with maintaining the poor repair
state of their equipment. With the addition of BPL,
how will power companies manage to stay within the radio interference
regulations set forth by the FCC?

I beleive BPL would be an unreliable system of delivery, and an
unneeded duplication of existing data services. It would interfere
with all shortwave radio services, including commercial, utility,
aircraft, rescue, and amateur radio services. Its effect on higher
frequency services due to harmonic interference remains to be seen.

In all, I think BPL is a unrequired, unpredictable technology and I
urge you to prevent BPL from polluting our nation's radio spectrum.

Agreed. If the idea is to pound in the old rod somewhere else, and is intended for radio ground purposes only, then it is much better left where it is. A single ground rod is practically useless for radio purposes. Unless immersed in salt sea water it is equivalent to a single shallow buried radial wire of slightly greater length. Just measure the resistance of one in average sort of soil at about 2 MHz. Use a hand-held antenna analyser on the impedance range and a bottom-loaded resonant vertical antenna. Or mess about with a pair of rods spaced apart 3 times their depth. You can crudely estimate local soil resistivity (or conductivity) by such means. Kneeling down, however, to read the meter in cold damp stoney soil can result in house-maid's knees. If you are short-sighted, as I am, then you have to lie on your belly. Keep all test leads short. The arithmetic is fairly simple. I can't understand why so many of you have never done it.

Before we go any farther, Walt, please reference a copy of _Optics_,
by Hecht. Dr. Best's equations are valid. He just didn't understand what
he was dealing with and presented them improperly. Hecht presents them
properly. Dr. Best's equations are the classical physics equations for
the destructive interference and constructive interference.

> With the transmission line system Steve's voltage V2 comes from the same source
> as V1.

Yes, V1 comes from the generator and V2 comes from reflections from the
load which come originally from the generator. Dr. Best didn't understand
the S-parameter analysis and presented his material in an invalid way. But
even though he didn't understand what he was saying, his equations are
valid. He was completely off base in his explanations. It was like
Einstein coming up with E = MC^2 and then completely blowing the
explanation.

In an S-parameter analysis, b2 = s21(a1) + s22(a2)

In Dr. Best's analysis, VFtotal = V1 + V2 where:
V1 = V1F*(transmission coefficient) + V2R*(reflection coefficient)

V1F is the voltage incident upon the impedance discontinuity from the left. (port1)
V2R is the voltage incident upon the impedance discontinuity from the right. (port2)

There's a one-to-one correspondence above. If the S-parameter analysis is
valid, then Dr. Best's equations are valid. He just didn't present them
in a valid manner.

> Because Steve used Eq 9 in an invalid way to derive Eqs 10 through 15, all of
> these derived equations are also invalid. Try Eq 13 for example. It says 75 w
> plus 8.33 w = 133.33 w, as you well know. This is absurd!

His equations are valid. His knowledge is what was invalid. It is true that

75w + 8.33W + 2*SQRT(75W*8.33W) = 133.33W

P1 + P2 + interference power = PFtotal

I presented this to Dr. Best 9 months before his Part 3 was
published. He simply didn't pay any attention.

From a voltage standpoint where ci means constructive interference:

V1^2/Z02 + V2^2/Z02 + Vci^2/Z02 = VFtotal^2/Z02

For a Z02 equal to 150 ohms (if I remember correctly)

106.07v^2 + 35.35v^2 + 86.6v^2 = 141.42v^2 So

V1^2 + V2^2 + Vci^2 = VFtotal^2

This is exactly what you have been saying all along, something that Dr.
Best simply didn't understand. He completely ignored the interference
term without which the voltage equation cannot balance.

2*SQRT(75W*8.33W) is the constructive interference term supplied by the
destructive interference event on the other side of the match point which
Dr. Best completely ignored in his article.

> In addition, because the powers don't add up correctly using V1 and V2 at zero

> power would be with the various phases. This is poppycock, because the phase
> relationship between the source (V1) and re-reflected voltage (V2) is ALWAYS
> ZERO on lossless lines.

Only if the system is perfectly matched. If the system is not matched, V1 and
V2 can have any phase relationship. Dr. Best's equations are valid but he just
didn't comprehend their meaning. When I called him on it, he seemed never to have
heard of destructive/constructive interference. That's what set me to researching
EM waves in the arena of optics.

I looked at the situation assuming that you two guys are both knowledgeable and
intelligent and I arrived at the conclusion that the two of you are only two inches
apart. But (IMO) neither one of you is willing to move that one inch to bridge the
gap. (I have said this before in private email to Walt.)

This is exactly the same mistake that Dr. Best made. *VOLTAGE DOESN'T RULE!*
Current is *equally* important to voltage. If you had assumed that "current
rules", you would be saying - "when the currents are 180 out of phase it
defines an open circuit".

My argument is actually a minor point but bridges part of the gap between
you and Dr. Best. (And absolutely nothing being discussed here concerns
the source impedance of a transmitter. All we are discussing is what
happens at a match point in a transmission line or at a tuner.)

Reg, the question (assertion) was yours. Now you have to defend it by
furnishing the impedance looking back toward the source and the impedance
looking toward the load. I can tell you what it is in my antenna system,
but not yours or anyone else's. In my system, the impedance looking back
toward the source is very low. The impedance looking toward the load is
between 25 ohms and 100 ohms. That's an ideal application for a balun.

> By the way, I'm on Blue Nun Merlot tonight.

I just finished off 5 liters of Almaden Cabernet Sauvignon. All I
have left in this dry county is Coor's light and Bella Sera Merlot.
That Italian wine is not as good as it used to be. They must have
changed from wooden barrels to mass produced metal vats.

There are half a jillion designs already out there. Also in books. All designs can scaled to any other frequency. IE: any 2 meter VHF antenna design can be easily scaled to 160 mhz. Why the rigid construction requirements?
If you are scaling a design to another freq, you should also scale the element dia. Luckily, there should be no need to change element diameter for a rescaled 2m antenna, as it's already close enough. I once built a marine band 4 element yagi from a thin copper tube as a boom, and coathanger wire soldered to the boom as the elements. Not the greatest materials, and it eventually rusted, but I could hear stuff that didn't exist on verticals. I'm in Houston, and was listening to marine traffic out towards Galveston, and the gulf. 50-60 plus miles easy... If you have NBS designs, what are you waiting for? Those spacings are quite

good enough. They do lean towards max gain vs f/b, but you don't need super f/b with what you are doing. So a NBS design should be fine. "the f/b is still about 10 db" Thats what I used. My 6m beam is also a NBS yagi. All my homebrew yagi's use a driven element grounded to the boom. Also, I use gamma or T matches, etc...I rarely use a split driven element insulated from the boom. It's more work, and I'm lazy...Only my store bought "I didn't pay for it" HF beam is built that way. MK

Many use welding rod for elements on VHF/UHF antennas. It's a good size.
You can build VHF yagi's totally from hard drawn copper tubing. Boom,
elements, gamma match, the whole thing. One piece, all welded together.
My 6m yagi is built that way from 1/2 copper for the elements. One inch
copper for the boom. Elements are brazed to the boom. I'd use much
smaller for VHF. You can get both 1/4 and 3/8 copper tubing. You could
use 1/2 inch for the boom. You want to use hard drawn copper. Preferably
not the soft stuff that is coiled. Although for VHF, even it would work
ok. But my 50 mhz yagi, I had to use hard drawn. It's too big for soft
copper. It would wilt...:(MK

That says that narrow bandwidth contributes to higher efficiency
which is how I always understood it.(Though many do not accept that)
But as you say it is a shorthand type statement.
My antenna on 160 is very narrow banded at any particular setting or
frequency
(two loops and a short dipole coupled in tight cluster form),when
modelled ,shows part of the current curve breaking out into a sino
soidal oscillation (no phase change) for portions of the antenna.
Such modelling, ofcourse, requires a large amount of points per unit
length for high accuracy and the occillation would probably not show
up visually if calculation points were reduced.
It does not seem to affect things in practice on the air but I have
often wondered what the consequences would be if the bandwidth was
narrowed even more and the current oscillation possibly propagate over
all the of the antenna !
With the current taking on an occillation it would suggest changes in
radiation

>the destructive interference and constructive interference.

I'm trying to locate my Hecht paper, but can't at the moment. Let's make sure we're talking about the same set of of equations. The ones I'm saying are invalid as stated in his article appear on Page 46, Col 2. These equations are all being used invalidly as a result of his Eq 9, Part 3 being invalid for use with reflected power with only one source. This a concept you're just going to have to learn to accept. This equation is valid ONLY when there are two separate sources--the rearward traveling reflected wave is NOT a second source, and it will NOT work on power contained in the reflected wave. You must understand why the invalidity of his Eq 6 in Part 1is responsible for the entire problem. Once you understand this point you'll understand why the equations on Page 46 are invalid.

Cecil, Steve's Eq 9 is valid only if there is more than one source. In this case there is only one, the transceiver. This a concept that you apparentely aren't getting, and Steve didn't either. Because Steve derived his Eqs 10 thru 15 from an invalid premise concerning Eq 6 those equations are invalid. Just plug his values for P1 and P2 into any of those equations and you'll get invalid answers.

>> With the transmission line system Steve's voltage V2 comes from the same source
>> as V1.
>
>Yes, V1 comes from the generator and V2 comes from reflections from the
>load which come originally from the generator.

But Cecil, you CAN'T add V1 and V2 in any manner to obtain forward power, because adding V1 and V2 does not yield forward voltage. This is the first place Steve erred in Part 1. Go back and review my previous msg where I explain why his Eq 6 in Part 1 is invalid.

Dr. Best didn't understand
>the S-parameter analysis and presented his material in an invalid way. But
>even though he didn't understand what he was saying, his equations are
>valid. He was completely off base in his explanations. It was like
>Einstein coming up with E = MC^2 and then completely blowing the

>
>In Dr. Best's analysis, VFtotal = V1 + V2 where:
>V1 = V1F*(transmission coefficient) + V2R*(reflection coefficient)

How many times do I have to explain that V1 + V2 does NOT equal VF total? This concept cannot be fudged into the S- parameter analysis, because V1 + V2 = VF total is an invalid premise.

>V1F is the voltage incident upon the impedance discontinuity from the left. (port1)
>V2R is the voltage incident upon the impedance discontinuity from the right. (port2)

I repeat, Cecil, V1 + V2 yields only the swr, not VF total forward voltage.

>There's a one-to-one correspondence above. If the S-parameter analysis is
>valid, then Dr. Best's equations are valid. He just didn't present them
>in a valid manner.

The S-parameter analysis would be valid if the premise that V1 + V2 = VF were valid, which it is not. Please review my explanation why his Eq 6 in Part 1 is invalid. This is the crux of the entire case, which has made the Eqs that I say are invalid, invalid.
>
>> Because Steve used Eq 9 in an invalid way to derive Eqs 10 through 15, all of
>> these derived equations are also invalid. Try Eq 13 for example. It says 75 w

>
>His equations are valid. His knowledge is what was invalid. It is true that
>
>75w + 8.33W + 2*SQRT(75W*8.33W) = 133.33W

This is Steve's Eq 12, which appears to be correct when theta = zero, but he qualifies this equation, saying tghat when V1 and V2 are in phase the total power can be determined by Eq 13. NOT SO. The ironic part of this is that when the system is matched V1 and V2 are always in phase on lossless lines.

>P1 + P2 + interference power = PFtotal

This fact is precisely what Steve emphatically denies,

>I presented this to Dr. Best 9 months before his Part 3 was
>published. He simply didn't pay any attention.
>
> From a voltage standpoint where ci means constructive interference:

I don't understand the ci term--please explain.

>V1^2/Z02 + V2^2/Z02 + Vci^2/Z02 = VFtotal^2/Z02

V1^2/Zo + V2^2/ Zo = total forward power. The left -hand terms of the above equation are power terms that do not equal VFtotal^2/Zo, because V1 + V2 does not equal VFtotal.

>For a Z02 equal to 150 ohms (if I remember correctly)
>
>106.07v^2 + 35.35v^2 + 86.6v^2 = 141.42v^2 So
>
>V1^2 + V2^2 + Vci^2 = VFtotal^2

Again, if V1 + V2 does not equal VFtotal, then the sum of the squares of V1 and V2 cannot equal the square of VFtotal, unless Vci^2 is a large negative number.
>

Yeah, but if V1 and V2 have any relationship other than zero the system is NOT perfectly matched.

Dr. Best's equations are valid but he just
>didn't comprehend their meaning. When I called him on it, he seemed never to have
>heard of destructive/constructive interference. That's what set me to researching

But Cecil, why would we be considering any condition other than perfectly matched? All of his equations from 9 thru 15 specifiy the route to obtain either PF or VF. This means conditions are for a matched system.

Source record: 93906

While trying to fix a minor problem on my vertical... I accidentally broke the threaded coupler between the bottom of the 75/80 meter resonator and the top of the lower section is screws into this coupler is now broken off 1/2 in the resonator the other 1/2 in the lower mating section. At first I assume I could use like an "easy out and turn the broken pieces out of each unit. This is not the case. the part broken in the resonator does turn easy but will not back out. I am assuming it is some how captured and may not be a threaded item anyway..

the part broken in the lower section I can not even get it to break loose and turn it..

I have though about using a drill and tap on both sections and then use a thread rod about 1 to 1.5 inches long ..

any ideas? am I missing something? any ideas and or fixes would sure be appreciated very much!!

thanks

Dan

>which is how I always understood it.(Though many do not accept that)

Hi Art,

When a low bandwidth antenna has very high efficiency (in the range of
95-98 percent), "more" efficient is not very remarkable.

The problem you are encountering is trying to equate bandwidth/Q with
efficiency. There is an old adage: correlation is not causation. A
successful antenna design is by definition lossy = radiation
resistance. You can reduce this loss to zero, boost the Q, make for a
very small bandwidth and come up with a very inefficient antenna.
Same thing goes for Tube finals' tuning. You don't want narrow
bandwidth/high Q because that means no power will leave the
transmitter. Q for the Finals falls between 10 and 15 because the
load must be a loss.

The coil/capacitor that makes up the finals tuning has an "unloaded" Q
that is high, which means that the coil/capacitor in and of itself
does not contribute to the loss, but as a system, Q is relatively low
(by at least a power of 10 if not 20). It would be impossible to
measure the unloaded Q of an antenna because it is necessarily MUCH
larger than a conventional coil/capacitor lumped circuit. Being large
means that it encompasses that loss of radiation resistance.

There is, of course, a hazy area where antennas get very small, or
finals get very big. The 1M loops sold as "magnetic" loops certainly
approach that, and yet the ratio of radiation resistance and loss
resistance in the low bands is clearly a loser proportion for this
breed. If you have no choice, even 5% efficiency is gold bond stuff.
However, simply because it has high Q does not elevate its poor
performance.

This returns us to that crude triad of pick any two characteristics
and leave the third for the vultures.

Walt, I'm sorry, all I have is the QEX CD and the pages are not the same as
they were in QEX magazine. Dr. Best's equations 13 and 15 are the classical
physics interference equations virtually identical to the irradiance equations
in _Optics_, by Hecht.

> But Cecil, you CAN'T add V1 and V2 in any manner to obtain forward power,
> because adding V1 and V2 does not yield forward voltage.

Yes, it does, Walt. Consider the following matched system similar to the
example in Dr. Best's article.

100w XMTR-----50 ohm line---x---1/2WL 150 ohm line---50 ohm load

P1 = 100W(1-rho^2) = 100(1-.25) = 75W

P2 = 33.33W(rho^2) = 33.33W*.25 = 8.33W

P1 = 75W, P2 = 8.33W, PFtotal = 133.33W

V1 = 106.07V, V2 = 35.35V, VFtotal = 141.4V

V1 + V2 = VFtotal, 106.07V + 35.35V = 141.4V

> How many times do I have to explain that V1 + V2 does NOT equal VF total?

But it does, Walt. See above.

>>75w + 8.33W + 2*SQRT(75W*8.33W) = 133.33W (Equation 13)
>
> This is Steve's Eq 12, which appears to be correct when theta = zero, but he
> qualifies this equation, saying that when V1 and V2 are in phase the total
> power can be determined by Eq 13. NOT SO.

Yes, it is, Walt. Equation 13 is valid for any matched system. That's
equation 13 just above. Perhaps you don't understand what Dr. Best means
by P1 and P2.

PFtotal = P1 + P2 + 2*SQRT(P1*P2) total forward power

133.33W = 75W + 8.33W + 50W

There's 50W of constructive interference and the equation balances perfectly.

Hi Thierry,

Yes, the cage idea should work well. I'd recommend 3 wires as the
very minimum, and I think 4 or more would be better. It also helps if
the form a cone, like the "Isopole" antennas, so the cage is well away
from the coaxial feedline, which would be centered in the cone.

If you use coax with a "copperweld" (copper-clad steel) center
conductor, perhaps you can strip 5 meters of the jacket and braid off
the end of the coax, and the coax is then one continuous run. In
fact, you can probably just cut the jacket and braid off of a short
section 5 meters from the end, to make the job easier. Then attach
some wires, even thin ones, to the feedline braid and run them back
along the line.

I'd recommend a choke balun, perhaps a few cm further along the line
from where the cage wires end. For single band use, you can coil up
some coax and even bridge across the coil with a capacitor to tune it,
connecting the capacitor to the braid -- that trick is useful if you
want to keep the coil small.

Cheers,
Tom

This is interesting. I toyed with the idea of disposable antenna
systems for VHF Field Days. They only have to survive for 24hours, but
have to be big, cheap and light weight. I came up with the idea of
wrapping kitchen foil onto the thin dowel used to support plants to make
the elements (maybe plastic drinking straws would do on 70cm) and make
the boom out of bamboo or plastic tubing using string and a t-bar to
stop droop and sideways bend.

I never pursued it, but the card idea comes close to what I was
thinking of. Anyone tried something more ambitious. ?

Mark

If I am prepared to go with other peoples electrical and mechanical designs
then there is no doubt my task ought to be easy peasy. And as you say there
are zillions of designs out there already.There is a heck of a lot of sense
in taking that approach. :c)

It's perhaps unfortunate that I was started off by being given a model to
run in a program. This may have complicated the approch uneccessarily and
taken me away from what was the more sensible approach.

So obtaining software models and messing with antenna programs is perhaps
rather a redundant exercise.

Thanks for driving that home to me.

Rich

3560. Scaling yagi antennas

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-06 10:59:10 UTC
From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <2igbn1Fmeti9U1@uni-berlin.de>
Source record: 93915

Strategy is that you don't rely on other peoples' software models. Because if you do you might find yourself having to engage in quite extensive design work, that is probably out of your skill range anyway. (Assumption is that there's no way that you can simply transfer dimensions from a software model to an actual antenna. This may be true to a greater or lesser extent.)

You decide on someone else's electrical and mechanical design. But the design is for another frequency. So, you chose a design closest to your frequency. This means you must scale the antenna.

Scaling simply invoves altering the dimensions proportionally. If the already designed antenna is for 144 Mhz and your desired antenna is for 159 Mhz then you have to scale size downwards by a factor of 144/159 = 0.90566.

If you were to scale to perfection every part of the antenna would be reduced in size, the boom, the element diameters etc. But this is not quite necessary in practice if there is no great difference in design frequency of the original antenna and your desired antenna frequency.

In the example given, concerning the element length, if the element lengths are reduced by 0.90566 then that should suffice. In other words, just altering the element lengths should suffice, no need to scale everying.

Yet, there may be times when you wish to alter the element and the boom sizes.

If the designed antenna is for a different frequency than what you want, changing the element lengths (again, sometimes you can get away by just changing the element lengths) is a matter of scaling.

However, you can also wish to change dimentions, but not scale the antenna. For instance, you want an antenna for 144Mhz, and you chose a 144Mhz antenna design, but you want to alter either the element diameters, or the boom size. Alteration of the element diameters will mean the length of the elements will have to change, to maintain resonance. Alteration of boom size will also have an effect on element lenghs. In this situation what you need is a G3SEK's program ELE.EXE which will calculate the new element length sizes when you alter either element diameter or boom size.

So, concerning the example: To get your 159 Mhz yagi antenna, you simpy scale the element lengths of the 144Mhz antenna. That should suffice as long as you keep to the original element diameters and boom.

However, if thereafter you wish to alter element diameters or boom size you have to use ELE.EXE. In that case you pretend that the scaled antenna is an original antenna. Remember, all you did was scale element lengths, nothing else, and because the scaling was minimal it's safe to say the scaled

antenna will work pretty close to the original. So when using ELE.EXE you take the scaled antenna as the original. But, you have to be carefull, changing the design configuration too much will not produce a good result. For instance, if you change the elements from going through the boom, to over the top of the boom, that may be a change too far.

This is how you "design" your antenna using someone elses original design. Well, it's how I think you do, not being an antenna buff.

Ian, G3SEK, can you say anything more about ELE.EXE. What can you alter, I presume the construction must remain the same, just that you may alter element diameters and boom size. What I want to do, is scale, and then possibly alter either all parasitic element diameters, keeping DE diameter the same, or just alter DE diameter, keeping parasitic element the same. Or alter both. Can ELE.EXE cope with that?

I put "scaling antennas" into Google and got a measly 18 hits. Probably because as a concept it's simple.

Perhaps there should be a word for scaling then altering element or boom diameters. A name given to this "design" approach. :c)

What I do wonder of whether these two things, scaling and altering element
diamer or boom size, is worth a dedicated webpage, uncluttered with other
design issues.

http://www.ifwtech.co.uk/g3sek/diy-yagi/index.htm

There is information here, but I'm saying could someone create a webpage
where the only issues are scaling and element and boom corrections. Where
there is nothing about construction, because you are going to stick to the
original construction, nothing about modelling, because that's not relevant.

The page is made for those persons who only wish to scale and alter element
diameters or boom from a published design. A page not cluttered with
superflous information, information that has nothing to do with what the
person needs to know.

One of the biggest problems I've had is when you scale the antenna from
a higher frequency down say 1296 to 432 you also scale the weight by a
factor of something like 27 (someone could build the weight -scale into
a program I suppose), and you usually don't want to that.

Dan -

It sounds like these parts have "seized"
(this happens with aluminum parts - if you do not use a product like
Pentrox-A by Burndy)

I had a similar problem with a threaded radial on a Cushcraft VHF/UHF
vertical.

Although I ordered a replacement radial, I had to slowly drill out the
broken radial
(patience and a drill press help) ... I did use a correctly sized tap to
clean the threads.

I then applied Pentrox-A to the threads when I reassembled the antenna.

>But it does, Walt. See above.

Well, Cecil, so far I haven't been able to follow the logic in the lines above. Perhaps they are correct for that particular example, but I'm not so sure. For example, if 100 w is available only 75 w will enter the 150-ohm line initially, so initially only 56.25 w is absorbed in the 50-ohm load and 18.75 w is reflected, which then sees a 3:1 mismatch on return to the 50-ohm line, making the re-reflected power 4 .69 w . I haven't had time to work through the remaining steps to the steady state. So before I do I notice that you state that Eqs 10 thru 15 are valid for any matched system. So let's see if this is so by using the example Steve used earlier in his Part 3, the one he took from Reflections and then called it a 'fallacy'.

This is that example: 50-ohm lossles line terminated with a 150 + j0 load. 100 w available from the source at 70.71 v. Matched at the line input, in the steady state the total forward power Pfwd = 133.33 w and power reflected is Pref = 33.333 w. With these steady state powers the forward voltage is 81.65 v and reflected voltage is 40.82 v. Due to the integration of the reflected waves the source voltage 70.71 increased 10.94 v to 81.65 v. Therefore, in the steady state V1 = 81.65 v and V2 = 40.82 v.

Now using V1 and V2 in Eqs 7 and 8 we get P1 = 133.33 w and P2 = 33.333 w. So far so good, these Eqs are correct and valid.

But now let's plug V1 and V2 into Eq 9:

(V1 + V2) = 122.47 v. Then 122.47^2/50 = 300 w. Something's amiss here. So let's go a step further and plug P1 and P2 into Eq 13:

P1 = 133.33 w and P2 = 33.333 w.
Then using Eq 13, PF total = (sqrt 133.33 + sqrt 33.333)^2 = 300 w.
We get the same incorrect value as with Eq 9. Now why can this be?

For starters, P1 derived from Eq 7 is already the total forward power. So why is the forward power value P1 plugged into Eq 13 do derive the total foward power PFtotal?

Do you see where this is going, Cecil?

So now let's go one step backward to use Eq 11:

Plugging V1 and V2 into Eq 11 we get VFtotal^2 = 14 ,999.6983 (call it 15,000). Therefore, VFtotal = sqrt VFtotal^2 = 122.4733 v.

This is the same incorrect value obtained using Eq 9.

So, Cecil, do you still believe these equations are valid for every matched situation?

Walt

Cecil, one point I forgot in the msg above--the standing wave.

Remember I said earlier that V1 + V2 yields the standing wave, not forward voltage Vfwd? We know that V1 + V2 = 122.47 v. This is the max value of the standing wave.

Now V1 - V2 = 40.82 v. Notice that (V1+ V2)/(V1 - V2) = 122.47/40.82 = 3. 0. Doesn't this look something like the SWR?

Are you talking about the two generators hooked up back to back.
If so, where are the two EM waves traveling in the same direction
which is a prerequisite for complete destructive/constructive
interference? The generated EM waves, in your example, are moving
in opposite directions which is simply not relevant to this discussion.

Please conjure up an experiment where two coherent waves are
moving in the same direction without affecting the generators.

Please pick any example of your choice of matched systems. Dr. Best's equation 13 will be valid for any matched system. VFtotal = V1 + V2 will be valid for any system, matched or not.

> For

When you do, you will get the same values as I.

As I have said before, Steve's equations are correct but he simply drew the wrong conclusions from them. His "fallacy" is a fallacy but has nothing to do with his equations. He simply drew the wrong conclusions from valid equations.

> This is that example: 50-ohm lossles line terminated with a 150 + j0 load. 100 w

> state V1 = 81.65 v and V2 = 40.82 v.

Nope, you simply misunderstood what Steve said. V1 and V2 are *NOT* on the 50 ohm line. In fact, the 1 WL 50 ohm line is irrelevant and just serves to confuse. V1 and V2 are voltages existing *at the match point* at the INPUT of the tuner. Steve chose an example that is virtually impossible to explain or understand.

Let's take it step by step starting with Steve's example:

100W XMTR---50 ohm line---tuner---1WL 50 ohm line---150 ohm load

The 1WL 50 ohm lossless line is irrelevant except for power measurements so eliminate it.

100W XMTR---50 ohm line---tuner---150 ohm load

The tuner can now be replaced by 1/4WL of 86.6 ohm feedline.

100W XMTR---50 ohm line---x---1/4WL 86.6 ohm line---150 ohm load
100W--> 107.76W-->
<--0W <--7.76W
V1-->
V2-->

Now we have an example that is understandable and we haven't changed
any of the conditions.

The magnitude of the reflection coefficient is 0.268. That makes the magnitude
of the transmission coefficient equal to 1.268 (Rule of thumb for matched
systems with single step-function impedance discontinuities)

So V1 = 70.7 * 1.268 = 89.6V V2 = VF2 * 0.268 = 6.95V

VFtotal = V1 + V2 = 89.6V + 6.95V = 96.6V

PFtotal = 96.6V^2/86.6 = 107.76W

> So, Cecil, do you still believe these equations are valid for every matched
> situation?

Yes, they are, Walt, once one understands them. I don't blame you for being
confused about Steve's example. He chose the worst example possible and
didn't explain it very well at all.

I still maintain that you two are two inches apart and neither one of you
will budge an inch.

> voltage Vfwd?

Dr. Best's V1 + V2 are moving in the same direction toward the load
and do NOT yield the standing wave. You have misunderstood what he
was trying to say (which is super easy to do).

Dr. Best's V1 is proportional to the S-parameter term, s21(a1)
The only difference is that all S-parameter voltages are normalized
to the square root of Z0.

Dr. Best's V2 is proportional to the S-parameter term, s22(a2)

Consider this easy-to-understand generalized example.

XMTR---Z01---x---1/2WL Z02---load=Z01
VF1--> VF2-->
<--VR1 <--VR2

VF1 is the forward voltage in the Z01 section. VF2 is the forward
voltage in the Z02 section. VR1 is the reflected voltage in the
Z01 section. VR2 is the reflected voltage in the Z02 section.

RHO is the physical reflection coefficient and TAU is the physical
transmission coefficient which is equal to (1+RHO) at an impedance
discontinuity.

Dr. Best's V1 = VF1(TAU) His V2 = VR2(RHO)

Dr. Best's V1 is the part of VF1 that makes it through the impedance
discontinuity (coming from the source side). It is traveling toward
the load.

Dr. Best's V2 is the reflected voltage re-reflected from the match
point. It is also traveling toward the load.

V1 and V2 superpose into VF2 which Dr. Best calls VFtotal. And that
is indeed what happens. That Dr. Best was somewhat incapable of
explaining the equation is his fault, not yours. His explanations
were so obtuse, I'm not sure he understood them himself. He certainly
didn't recognize the classical interference equations as such.

Well, let's see.

V1 = VF1(TAU)

V2 = VR2(RHO)

[VF1(TAU) + VR2(RHO)]/[VF1(TAU) - VR2(RHO)]

Does that look something like SWR?

Cecil, Steve's equations 4 thru 8 are correct, valid, and completely GENERAL. In
the text preceding the Eqs he even specifies Zo as 50 ohm, not that it matters.
He correctly defines V1 in Eq 7 and he correctly defines V2 in Eq 8. However, he

makes a vital error in the paragraph preceding these two equations.

He says incorrectly, "When two forward traveling waves add, general superposition theory and Kirchoff's voltage law require that the total forward-traveling voltage be the vector sum of the individual forward-traveling voltages such that VFtotal = V1 + V2."

This statement is TOTALLY FALSE, and this error is the basis for the remainder of his equations to be invalid. Kirchoff's voltage law does not apply in this case of transmission line practice. There are times when circuit theory doesn't hold and transmission line theory is required.

You are still ignoring his Eq 6 in Part 1, which is false and invalid because he mistook the expression for determining the standing wave for the total forward wave. Look back at my previous msg where I've shown that the addition of the forward and reflected waves yields the standing wave, not the forward wave. The standing wave is NOT the forward wave.

Refer to the text on your CD at the paragraph that begins: "A transmission line system analysis must be performed with voltage and current, from which the power is then derived." Read on from this point to where it reads, "If total re-reflection of power occurs at the T-network, the re-reflected voltage must have the same magnitude as the reflected voltage."

Please note the values of voltages and currents that appear in that entire section, because this section is a direct copy of my example he took from Reflections in an attempt to disprove it. Which he does in the next sentence:

"Therefore, based on the assumption that total power re-reflection and in-phase forward-wave addition, the total forward-traveling wave of 81.65 v must be the result of a voltage having a magnitude of 70.711 v adding in phase with a voltage having a magnitude of 40.825 v. Two in-phase complex voltages having magnitudes of 70.711 v and 40.825 v cannot add together such that the resulting voltage has a magnitude 81.65 v."

OF COURSE IT CAN'T, because these two voltages CANNOT BE ADDED TOGETHER TO DERIVE THE FORWARD VOLTAGE.. This is further evidence that he didn't realize that Eq 6 in Part 1 was wrong, because it derives the standing wave voltage, NOT THE FORWARD VOLTAGE.

He then goes on in an unsuccessful attempt to prove my method wrong, in which he gets himself into trouble with those equations that don't work in general. If you still don't see the problem, Cecil, please go back and review my analysis in the earlier post and explain to me why you disagree with my results that show conclusively that the equations don't work.

To conclude, I have shown you why I have not used his values of V1 and V2 incorrectly, as you say. If you can show that I'm wrong I'll take the time to study the step-by-step in your example below.

Walt

I think there is definitely a kinship there. Folding
back the dipole "legs" makes the dipoles less directive
and it becomes possible to use only two dipoles rather
than the four of the Lindenblad.

Of course, when I look at a Lindenblad in a certain
way, it appears to be a highly truncated, half-wave
section of a quadrifilar helical antenna radiating
in the normal (radial) mode. You have to tilt your
head just right to see it.

Steve is essentially doing an S-parameter analysis without the (square root of Z0) normalization. Since we know that an S-parameter analysis of a match point is indeed valid, a lot of Steve's equations are valid by association.

Assuming the S-parameter equation is valid, we can use it to prove that

VFtotal = V1 + V2

V1/SQRT(Z0) = s21(a1) in the S-parameter analysis.

V2/SQRT(Z0) = s22(a2) in the S-parameter analysis.

VFtotal/SQRT(Z0) = b2 in the S-parameter analysis.

Given: b2 = s21(a1) + s22(a2) is a valid S-parameter equation.

Therefore, VFtotal/SQRT(Z0) = V1/SQRT(Z0) + V2/SQRT(Z0) is a valid equation because there is an EXACT one-to-one correspondence to the S-parameter equation.

Therefore, if we multiply both sides by SQRT(Z0) we get VFtotal = V1 + V2

The only way for the above equation to be wrong is if the S-parameter equation is wrong. The only difference in the S-parameter equation and Dr. Best's equation is the normalization by [SQRT(Z0)].

Given a generalized matched system:

XMTR---Z01---x---1/4WL Z02---load
VF1--> VF2-->
<--VR1 <--VR2

VF2 = VF1(TAU) + VR2(RHO) = V1 + V2 Dr. Best's equation

b2 = s21(a1) + s22(a2) S-parameter equation

Dr. Best is essentially quoting an S-parameter analysis

Cecil, if the S-parameteri analysis is applied correctly the results of the S-parameter analysis should agree with the results of mine that appears in my earlier posts. You have not responded to the results of my analysis that proves Steve's use of the equations 9 thru 15 is incorrect. I've proved that these equations do not work in general. Referring to my analysis, please show me where I went wrong, if that's your position.

Walt

> equations do not work in general. Referring to my analysis, please show me
> where I went wrong, if that's your position.

I thought I did that, Walt. Your V1 and Dr. Best's V1 are NOT the same quantity.
Your V2 and Dr. Best's V2 are NOT the same quantity. It is no wonder that you
didn't get the same results. The 1WL 50 ohm line in Dr. Best's example is
absolutely irrelevant. Calculating anything on that line is a waste of effort.

Please center your calculations around the match point.

Plug any values into the following generalized matched system:

```
Z0-match
XMTR-----Z01-----x-----1/4WL Z02-----load
VF1--> VF2-->
<--0V <--VR2
```

VF2 = VFtotal in Dr. Best's article traveling toward the load

VF1(TAU) = V1 in Dr. Best's article traveling toward the load

VR2(RHO) = V2 in Dr. Best's article traveling toward the load

VR2 will always equal VF1(TAU) + VR2(RHO) = V1 + V2

just like b2 will always equal s21(a1) + s22(a2)

Hmm I don't know where you are coming from but I ouldn't put my
antenna
in the CFA group that you state above. I know in the past that your
antenna is better than mine which is O.K. but the fact is that many
amateurs like to experiment and also pursue the "holy grail" Each
attempt provide knowledge
which is why antennas are pursued so much .I wager that the patent
pending
aproach discussed will provide welcome reading for everybody on this
newsgroup.
As for my particular antenna pursuit I am still not ready to throw it
into the dustbin as every change provides new insights on antennas (
the sinosoidal current wave for one)
I use my present antenna in the rotatable form on the top of the tower
for convenience but I modelled it after reading your comments and they
are as follows

Top band....vertical orientation
Impedance 349 +j41 ohms (186-j13 ohms when horizontally oriented
on the tower)
Load losses 2.88 db
Efficiency 51.5%
Radiation peak 23 degrees elevation -1.53dbi

The above has bandwidth of around 5 Khz which is O.K. for audio,
and frequency of use is selectable across the band.

Since the feed point is at the center I don't have to tear up the lawn for those rotten radial wires.
Efficiency jumps to over 90% on 80 meters and other bands with the typical figure eight form pattern, but my primary pursuit is on top band.
Yes, the antenna can be beaten when following conventional design but the hunt
using unconventional designs is part of the excitement, where slight change of inductance value moves you along the band /bands with out restriction with respect to power , the requirement of high voltage capacitors or large areas of grounding systems.
My antenna may be regarded as 'useless' by many but, unlike the CFA and other antennas you placed me with, my antenna is in use and the impedances provided seem to match those given by modelling using a PRO antenna program and using maximum segments because of the UNCONVENTIONAL close coupled cluster design.
Unconventional design provides insights to antennas like the oscillations that I refered to earlier, which is not to be seen on conventional designs and for which I seek further understanding and explanation.
The new unconventional design from R.I. which is 'patent pending' no less may well provide further insights that we are unaware of.
Unfortunately his efforts WILL be ridiculed by those who know that 'every thing about antennas is known' and by sharing he has shown his personal foolishnes to his peers.
When will the amateur learn that it is a waste of time to experiment where the failures are heralded and the minutia of new facts are ignored ???
Please forgive me for writing this extra post which has strayed from my original post.

Cecil, it seems like we're going around in cirles.

If Steve's equations are valid they should work in general. It doesn't matter whether we use the values from his T network section that comes later, or the values in my example that he attempts to prove incorrect.

What does matter is that the equations must deliver the correct answers regardless of the values used in the equations. I have proved that valid values plugged into his equations don't yield the correct answers.

Cec;il, why are you avoiding trying to understand the basis for his erroneous concept of adding forward and reflected voltages to obtain total forward voltage? You don't even respond to my discussion on this point.

This reveals the tower is a significant radiator and a necessary
adjunct for the operation of the antenna. This is an identical
characteristic of CFA's, EH's and fractals.

>Unconventional design provides insights to antennas like the

Walter Maxwell wrote:
> Cecil, why are you avoiding trying to understand the basis for his erroneous
> concept of adding forward and reflected voltages to obtain total forward
> voltage? You don't even respond to my discussion on this point.

I'm not trying to avoid it, Walt. Dr. Best simply doesn't do that. V1 is a *forward-traveling voltage*. V2 is a *forward-traveling voltage*. Their sum is VFtotal, the *total forward-traveling voltage*. He does NOT add a forward voltage to a reflected voltage. V2 is the *forward-traveling* re-reflected voltage equal to VR2(RHO).

When the reflected voltage is acted upon by the reflection coefficient, it becomes a forward-traveling voltage. That you think Dr. Best is adding forward and reflected voltages, is the source the present misunderstanding. The individual Poynting Vector for V1 points toward the *load*. The individual Poynting Vector for V2 points toward the *load*. V1 and V2 are coherent component waves, both flowing toward the load so, of course, they superpose.

Again, consider the following *matched* configuration where RHO is the reflection coefficient and TAU is the transmission coefficient.

XMTR---Z01---x---1/4WL Z02---load
VF1--> VF2-->
<--VR1 <--VR2

There are four superposition components that occur. Two of them are traveling toward the load and two of them are traveling toward the source.

V1 = VF1(TAU) traveling toward the load
V2 = VR2(RHO) traveling toward the load

Adding these two forward-traveling voltages yields VF2 = V1 + V2

V3 = VF1(RHO) traveling toward the source
V4 = VR2(TAU) traveling toward the source

Adding these two rearward-traveling voltages yields VR1 = V3 + V4 which, in a matched case is zero because V3 = -V4.

VF1 breaks up into two components, V1 toward the load and V3 toward the source.

VR2 breaks up into two components, V2 toward the load and V4 toward the source.

Collect and superpose the two forward-traveling terms and you get the total forward-traveling voltage.

Collect and superpose the two rearward-traveling terms and you get
the total rearward-traveling voltage.

Cecil, I know V2 is the re-reflected voltage, but what I'm trying to persuade you is that they do NOT superpose to form the forward voltage--they superpose only to form the standing wave. You've go to accept that the standing wave voltage is NOT the forward voltage. If you can't come to realize this is the key to the problem I'm going to have to give up.

Incidentally, you say tau is 1+ rho as the transmission coefficient, which when muliplied by input voltage yields forward voltage. I thought (1 - rho^2) is the transmission coefficient. These two terms are not equal. Can you explain the difference?

Walt

Amplified indoor RC antennas are, in my experience, a rather poor-performing product family in general. This seems to me to be a fundamental problem - it's not just an implementation glitch with one or another variety.

The problem is this: in many indoor situations, there just isn't enough clean, reflection-free RF for many stations present, above the local ambient noise floor. The signal present is badly contaminated by noise, and by reflections of the signal from nearby buildings (multipath), even before it hits the antenna. In these cases, it really doesn't help matters all that much to amplify the noisy/ghost-filled signal before sending it to the TV set - you boost the ambient noise and the ghosts, along with the desired signal.

In some cases, with some TVs, I gather that the amplification can help somewhat (some TVs seem to have poor RF front-end gain), but in other cases the amplification either doesn't help, or makes matters worse (by overloading the TV's tuner with other, stronger signals on nearby channels).

There's not really a good substitute for an antenna with good directional gain, mounted up as high as is practical on the roof, and aimed properly.

I duly note your judgement which appears to be based on the feed impedances
provided. For the record the vertical was modelled
with one end about two feet above the ground (over perfect ground) whereas
the horizontal form was modelled at 820 inches above ground , again over
"perfect ground". I look forward to when the initial 'new' technology
alluded to in this thread is available for full discusion.

I'm sorry, Walt,
Your belief that V2 is a reflected wave is the root of the misunderstanding.
V2 is a re-reflected wave and is therefore forward-traveling toward the load.
V2 is equal to the reflected wave voltage multiplied by the reflection
coefficient. V1 and V2 are traveling in the same direction, toward the load.

> Incidentally, you say tau is 1+ rho as the transmission coefficient, which when
> muliplied by input voltage yields forward voltage. I thought (1 - rho^2) is the

(1-rho^2) is the POWER transmission coefficient. For a single impedance
discontinuity situation, 1+rho is the VOLTAGE transmission coefficient.
From the IEEE Dictionary: "transmission coefficient, ... Note 2, An interface
is a special case of a network where the reference planes associated with
the incident and transmitted waves become coincident; in this case the
voltage transmission coefficient is equal to one plus the voltage
reflection coefficient."

Here is a description of this antenna by Peter Onnigian, P.E., who developed and patented the design:

+ +
(Onnigian) Shunt Fed Slanted Dipole Antennas
The slanted dipole antenna in its present configuration was developed and patented in 1970. It consists of 2 half-wave dipoles bent 90°, slanted and fed in phase.
The slant angle is critical as it is the factor which determines the ratio of vertically and horizontally polarized radiated power. The phase point center is at the feed insulator on the dipole support arm. When fed through a vertical support pole on which the antenna was mounted during initial development tests, the axial ratio varied less than 1 dB.
The commercial adoption uses a horizontal boom containing a step transformer. This boom supports two half-wave dipoles in which the included angle is 90°. The two sets of dipoles are rotated at 22.5° from the horizontal plane. Two opposite arms of the dipoles are delta matched to provide a 50 ohm impedance at the radiator input flange. All four dipole arm lengths may be adjusted to resonance by mechanical adjustment of the end fittings. Shunt feeding, when properly adjusted, provides equal currents in all four arms resulting in excellent azimuth circularity.
+ +

(RF) The <1 dB axial ratio of this configuration is reduced by the adjacent transmission line(s), and the tower structure needed to support it (as with all sidemounted radiators).

NEC-2 patterns for this design, and three others commonly used in FM broadcast transmit antenna arrays are shown in paper 10 at the link below. Paper 6 shows examples of sidemount antenna pattern distortions from the line and tower.

Cecil, please read me in the first paragraph. By Steve's own words he says the re-reflected wave must equal the reflected wave. This means the system is matched in his account. Therefore, V2, is not the root of any misunderstanding in my part.

You are still not getting the picture concerning that V1 and V2 cannot be added to establish the forward wave, as Steve incorrectly believes, they add only to form the standing wave.

I'm sorry that I didn't think of this earlier that Steve copied his Eq 6 in Part 1 from Johnson, except he placed Vfwd, the forward voltage, instead of E for the standing wave voltage. Look it up in your Johnson on Pages 99 and 100. He derives Eq 4.23 (the Eq Steve misunderstands) on Page 99, and expresses it on Page 100. However, note on Page 98, the beginning of Sec 4.2:

"The equations for E and I along the line can be expressed...."

So Cecil, please understand that this equation does NOT yield the forward voltage, as Steve believes, which is the root of his misunderstanding throughout his entire paper.

Concerning tau, I've seen it described in an HP App Note, which I didn't bring to Michigan, but I've never used it. However, if the power transmission coefficient is (1 - rho^2) the coefficient is 0.75 for rho = 0.5. Therefore, for 100 w forward only 75 w are delivered. This condition is shown valid experimentally.

Now let's use tau = 1 + rho as the voltage transmission coefficient. I interpret this to mean tau x input voltage = forward voltage arriving at a mismatched load. For a 100 w source at 50 ohms with the same rho as above, we have 70.71 x 1.5 = 106.07 v. But we know that the forward voltage on a matched 50-ohm line with rho = 0.5 is 81.65 v. Why the difference?

I should have been more aware of the explanation in the HP App Note--there must be a reason shown there to explain the difference.

Walt

> Another way of saying "You are right, Walt, you are wrong."

It's a very minor mistake, Richard, and one easily made. If you have
a copy of Dr. Best's QEX article, please feel free to express your
take on this discussion.

Let's see if I can present superposition in ASCII graphics. rho
is the voltage reflection coefficient and tau is the voltage
transmission coefficient. Assume VF1 has a phase angle of zero
degrees. Phase angles are important in the following but since
the system is matched, all phase angles are either at zero degrees
or at 180 degrees at the match point. So a sign change is equivalent
to a 180 degree phase shift.

100W XMTR---50 ohm line---x---1/2WL 150 ohm line---50 ohm load
VF1=70.7V--> VF2=141.4V-->
<--VR1=0V <--VR2=70.7V

According to the rules of superposition, the two voltages incident
upon 'x', VF1 and VR2, can be considered separately and then added.

Breaking VF1 down into its two superposition components yields:

x
|
VF1=70.7V (100W)-->|
|--> V1=106.06V (75W)
V3=35.35V (25W)<--|
|

VF1 = 70.7V at zero degrees (100W)

V1 = VF1(forward-tau) = 70.7(1.5) = 106.06V at zero degrees (75W)

V3 = VF1(forward-rho) = 70.7(0.5) = 35.35V at zero degrees (25W)

Note that PF1 = 100W = P1 + P3 = 75W + 25W

Breaking VR2 down into its two superposition components yields.

```
x
|
|<-- VR2=70.7V (33.33W)
V4=35.35V (25W)<--|
|--> V2=35.35V (8.33W)
|
```

VR2 = 70.7V at 180 degrees (33.33W)

V2 = VR2(reverse-rho) = 70.7(-0.5) = 35.35V at zero degrees (8.33W)

V4 = VR2(reverse-tau) = 70.7(0.5) = 35.35V at 180 degrees (25W)

Note that PR2 = 33.33W = P2 + P4 = 25W + 8.33W

Now, following the rules of superposition:

To get the total forward voltage, add V1 + V2

VF2 = V1 + V2 = 106.06V + 35.35V = 141.4V (133.33W)

To get the total reflected voltage, add V3 and V4

VR1 = V3 + V4 = 35.35V - 35.35V = zero volts (0W)

Note: Dr. Best neglected to mention P3 and P4 in his QEX article.
P3+P4 is the interference joules/sec. They are scalar values.

All voltages are consistent and all powers are consistent.

So, in this matched system, all reflected power is re-reflected:

PF2 = 133.33W = P1 + P2 + P3 + P4 = 75W + 8.33W + 25W + 25W

PF2 = P1 + P2 + (complete constructive interference) = 133.33W

PR1 = P3 + P4 - (complete destructive interference) = zero watts

Note that the voltage forward-rho = (150-50)/(150+50) = +0.5

reverse-rho = (50-150)/(50+150) = -0.5 (180 deg phase shift)

Walter Maxwell wrote:
> Cecil, please read me in the first paragraph. By Steve's own words he says the
> re-reflected wave must equal the reflected wave.

No, he says that is a fallacy. He says the re-reflected wave equals the
reflected wave multiplied by the reflection coefficient. His example is:
reflected power = 33.33W, re-reflected power = 8.33W

re-reflected power = 33.33W(rho^2) = 33.33W(0.25) = 8.33W
Here's what Dr. Best said in his QEX article, Part 3: "When two forward-traveling
waves add, general superposition theory ... require(s) that the total forward
traveling voltage be the vector sum of the individual forward-traveling voltages
such that VFtotal = V1 + V2." He clearly implies that V2 is a forward-traveling
wave and it is. Numerically, it is equal to the voltage reflected from the load
multiplied by the reverse reflection coefficient. In S-parameter terms, V2 is
the s22(a2) term.

> Concerning tau, I've seen it described in an HP App Note, which I didn't bring

Yes, 100W(0.75) is perfectly consistent with 70.7V(1.5)^2/150 where Z0=150 ohms

> Now let's use tau = 1 + rho as the voltage transmission coefficient. I interpret
> this to mean tau x input voltage = forward voltage arriving at a mismatched
> load.

No, no, no. Mistaken interpretation.

tau x input voltage = V1 (not the total forward voltage)

rho x reflected voltage = V2 (re-reflected)

V1 + V2 = forward voltage arriving at a mismatched load

V1 is proportional to the S-parameter term, s21(a1) where s21 is the forward-transmission
coefficient.

V2 is proportional to the S-parameter term, s22(a2) where s22 is the reverse-reflection
coefficient.

b2 is the total forward voltage arriving at a mismatched load.

VFtotal = V1 + V2 is virtually identical to b2 = s21(a1) + s22(a2)

Cecil, it is clear that you are not reading my posts!!!

You quoted Steve above, but I quoted the SAME quote earlier, explaining that he is WRONG. Please reread my quote. General superposition theory does NOT require that the forward voltage be the vector sum of the individual forward-traveling voltages.

When are you going to understand that that superposition yields the standing wave, NOT the forward wave? I've told you this over and over again, but you apparently aren't listening.

Cecil, please go to Johnson as I pointed out earlier and become educated as to where Steve screwed up.

Walt

Both descriptions are valid. Both denote that an application has been made. No legal right of property has been assigned by the USPTO under these.

'Patent applied for' is less used compared to 'pat pending'...

I know why - because it's the only way you can understand. It just doesn't happen to be true - as evidenced by the lack of any physical explanation for it.

Walter Maxwell wrote:
> But when the system is matched the reflection coefficient is 1.0.

Not in an S-parameter analysis which is essentially what Dr. Best is doing. He is dealing with the PHYSICAL reflection coefficient, (Z2-Z1)/Z2+Z1), not the virtual reflection coefficient based on reflected power being zero. This may be the source of the misunderstanding between you two. His reflection coefficients, like the S-parameter reflection coefficients, don't change from startup to steady-state. They remain constant even when no signal is present.

> General superposition theory does NOT require
> that the forward voltage be the vector sum of the individual forward-traveling

Superposition of two individual forward-traveling voltages requires that the sum be the vector sum as long as the interference energy requirements are met.

> When are you going to understand that that superposition yields the standing
> wave, NOT the forward wave? I've told you this over and over again, but you
> apparently aren't listening.

I am listening, Walt, and still telling you that you are wrong about that concept. Superposition of two waves traveling in opposite directions yields the standing wave. Superposition of two coherent waves traveling in the same direction yields DESTRUCTIVE/CONSTRUCTIVE INTERFERENCE, not standing waves.

> Cecil, please go to Johnson as I pointed out earlier and become educated as to
> where Steve screwed up.

I know where Steve screwed up, Walt, and he did screw up. But it wasn't in the area of an S-parameter analysis in the forward direction. It was in the rearward direction that he screwed up royally.

In the afore-mentioned example, the four powers associated with the four superposition voltages are P1, P2, P3, and P4. P1=75W, P2=8.33W, P3=25W, and P4=25W.

P1+P3 = 100W = generated power

P2+P4 = 33.33W = power reflected from the load

Dr. Best tell us that 75W+8.33W+2*SQRT(75*8.33)=133.33W and that is mathematically true.

What Dr. Best doesn't tell us is that 2*SQRT(75*8.33) = P3+P4 and that they are the interference component powers from classical optics theory.

You are grouping the powers together in this manner, (P1+P3)+(P2+P4)=133.33W
and that is perfectly true mathematically.

Both of you are doing essentially the same thing but neither one of you
realizes it. You guys are two inches apart and don't know it. It feels like
I am listening to two flatlanders argue about the third dimension.

The 'why' is conservation of energy. If there are only two directions
available and energy was traveling in one direction and now it isn't,
it's a no-brainer to realize that it must have changed directions.

I'm sorry that you don't believe in the conservation of energy theorem,
Jim. Do you boss know that?

So far you have failed every challenge to disprove the why. Wonder why?

Dr. Best is using physical reflection coefficients, aka an S-parameter analysis, which are never 1.0 in a system with a mismatched load.

Cecil, you're not even close to knowing where Steve screwed up. And you won't know until you follow my directions and go to Johnson and read what I said to read. I can't understand why you refuse to go in that direction. Because you refuse we're going around in circles. This has to stop.

What Johnson and I are trying to tell you is that the superposition of the source voltage and the re-reflected voltages DO NOT establish the forward voltage. Steve used Johnson's Eq for determining the standing wave voltage at any point on the line incorrectly as the forward re-reflected voltage wave V2. THIS IS WHERE HE SCREWED UP, CECIL., SCREWING UP THE ENTIRE ARTICLE !!

Thankfully you're the only one who deludes himself with this notion,
Cecil. Energy moves from source to load. It doesn't bounce back and
forth on it's way. That's what my "boss" believes - as I have explained
to you previously, in great detail.

Cecil, I think a more convincing argument is that I can take a slotted line
and directly measure a standing wave on it. A wave traveling in one
direction can not do that. Or am I cunfusing things?

If Johnson really said that, he screwed up because he is in direct contradiction to the S-parameter analysis described in Ramo, Whinnery, and Van Duzer in _Fields_and_Waves_in_Communications_Electronics_, (c) 1965, page 603, Section 11.09 "Scattering and Transmission Coefficients".

You and Dr. Best obtain the same component powers. You just group them differently. You guys are two inches away from agreeing.

Please provide the location of the Johnson quote details again. I sort by date and cannot find your Johnson reference even when sorting by threads.

No. That's right. But the point is - how much energy is actually
moving past the probe? Cecil seems to believe that a standing wave is
more than a superposition of voltages. It would be easy to mistake that
as a superposition of energies. But one can only superpose vector
quantities.

No Cecil, Johnson didn't screw up. Incidentally, the equation in question is his Eq. 4.23, derived on Pages 98 and 99, and displayed on Page 100. Steve screwed up because, as I've been repeating, he misinterpreted the equation to determine the forward wave instead of the standing wave.

From all of your statements so far, it appears you may have misunderstood what the forward wave really is. Here's a clue. When a tuner is properly adjusted in matching a 50-ohm line to a 150 + j0 resistance and the output voltage of the source is 70.71 v. the forward voltage is 70.71 x 1.1547 = 81.65 v. Do you recognize it or know where the 1.1547 came from ? Steve doesn't have a clue.

whoa
system is: source - line - load
If there are impedance mismatches, in the steady state (ie 3 microseconds
after key down);
There will be more energy in the transmission line and the source than there
would be if all the impedances were matched.
This is necessary to satisfy the boundary conditions imposed on Maxwell's
Equations at each end of the transmission line.

The losses are the rent you pay for storing the energy; See bazookas for a
good example.

To the radiated energy moving past the probe one must add the losses.

That's why I prefer antennas with no reflections.
Reflect on that.

If you really want a book Paul Dirac's "Quantum Mechanics" is sweet.
Or Hawking's "The Large Scale Structure of Space-Time."

My cat, Hiram P Maxim (Max for short, he likes sleeping on the S-Line I've
had since '63), just walked over the keys and approves.

Cecil,

I am happy to see that we are in agreement on this long-standing argument.

I explained this to Walt in some private e-mails about 18 months ago, and I wrote similar explanations in this group. I was vilified by both Walt and you.

I will summarize once again.

Both the Walter Maxwell model and the Steve Best model for this transmission line problem work correctly. They are internally self consistent, and they give the same physical answers. They obey the standard laws of physics and mathematics. However it is not possible to mix-and-match the models, using equations and definitions from one model in the other.

Walt continues to mis-read Steve Best's QEX articles. He needs to throw away all of his pre-conceived definitions about the meaning of specific Vx components and read exactly what Steve wrote.

Exactly, it is also a superposition of currents in phase with
the voltages. V*I*cos(0)=power

Everyone, including you, gets into trouble by completely ignoring
the superposition of currents. When are you (and your boss) going
to stop violating the laws of physics?

On page 99, in between equations 4.22 and 4.23 is an equation presented by
Johnson that is close to Steve's equation to which you are objecting.

> From all of your statements so far, it appears you may have misunderstood what
> the forward wave really is. Here's a clue. When a tuner is properly adjusted in
> matching a 50-ohm line to a 150 + j0 resistance and the output voltage of the

> recognize it or know where the 1.1547 came from ? Steve doesn't have a clue.

The forward voltage wave equals s21(a1)+s22(a2) which is virtually the same
as V1+V2 because V1/[SQRT(Z0)] + V2/[SQRT(Z0)] = s21(a1) + s22(a2). It's the
old one-to-one correspondence rule.

As I said before, Walt, the 1WL section of 50 ohm line in Steve's example
is *completely irrelevant* to the discussion. Steve only included that line
so the forward/reflected power could be measured and the impedance reproduced.
As long as you allow that 1WL of 50 ohm line to enter into your thinking and
calculations, you will never understand what he was trying to say. Please remove
the 1WL of 50 ohm line and please re-think your position. All the conditions
discussed by Steve occur at the *MATCH POINT* which, I think you will agree,
is NOT on the 50 ohm line.

But how can Steve deny the 100% re-reflected energy premise when
all the energy winds up at the load? How did it get to the load
if it was not re-reflected at the match point? TV ghosting proves
that it is indeed re-reflected at the match point.

Yes, that is the basis of my earlier challenge. Nobody has been able to provide a standing wave not composed of a forward-traveling wave superposed with a rearward-traveling wave. I have offered anyone and everyone $100 who can accomplish that in a single-source/single transmission line/single-load system. So far, no takers. One wonders why, considering all the gurus on this newsgroup. What I get instead are obfuscations of how waves can exist without energy.

H., there are standing waves all over a dipole antenna.
Its traveling-wave feedpoint impedance is about 600 ohms.
Only the reflections from each end of a dipole lower the
feedpoint impedance to 50 ohms or so. The reflected current
arrives back in phase at the feedpoint and the reflected
voltage arrives back out of phase. You can thank destructive
interference for the low feedpoint impedance of a dipole.

If you don't like reflections, you don't like a dipole and
should probably try a terminated rhombic. :-)

Hello again Gene,

What Steve wrote exactly, Gene, and I have read it exactly, over and over again, is based entirely on an invalid premise that you and all the rest who, like you, have expressed the notion that Steve's paper is the 'most brilliant and definitive paper ever written on the subject. Unfortunately, it's both ironic and tragic that a person so brilliant a mathematician, and knowledgeable in transmission line technique, should make such a grievous error in formulating the basis for his entire paper. It's also tragic that all of you who think his article is so great also made the same error in not recognizing the problem in the First Part of the article, his Eqs 6, 7, and 8, because they are invalid.

Steve used an equation in Johnson's "Transmission Lines and Networks" as the foundation for the entire paper. But unfortunately he misunderstood the meaning of the equation. He misunderstood it as early as 1998 when I pointed out why he misunderstands it, but he denied that he misunderstands it , stating that it is I who misunderstands it. Not a chance.

The equation he misunderstands is Eq 4.23 on Page 100 in Johnson, which is explained and derived on Pages 98 and 99, to derive the voltage E of the standing wave for any position along a mismatched transmission line. Steve's misunderstanding is that he believes the equation expresses the value of the forward voltage on the line. Consequently, his Eq 6 in Part 1 says that 'Vfwd = the terms on the right-hand side of the equation copied from Johnson', while the correct version is 'E = the terms on the righ-hand side'.

The difference between 'E' and Vfwd is so significantly different as to be unbelievable that he, of all people, used it for this purpose, and it is also unbelievable and shameful that you experienced engineers failed to recognize, not only the error in Steve's equation, but the ramifications it had on the domino effect on the remainder of his paper, especially making his equations 9 thru 15 in Part 3 invalid for general use.

I'd like for you and Cecil, and any other reader who believes Steve's paper is correct, to rethink the definitions of the standing wave and the forward voltage with the view toward another review of the paper. Then make that review and see if you still believe the material appearing there is correct.

If you then still believe the paper is correct I'd like for you to let me know the technical reason why you believe it's correct so that I can discuss it with you. It's really worth that effort--don't just blow it off as another rant and rave from Walt Maxwell.

Thanks for listening to what I think is an important issue.

Walt

Good luck. There are a few "engineers" here I would let touch my toaster.

Johnson's equation contains all possible components - both forward and
reflected, so Johnson's equation predicts the total net standing-wave
voltage. (Note that Johnson's equation contains both positive and negative
exponents.)

Dr. Best's equation contains only the forward components of Johnson's
equation. Therefore, Dr. Best's equation predicts *only* the forward-
traveling voltage. (Note that Dr. Best's equation contains only negative
exponents and represents the E+ half of Johnson's equation while omitting
the E- half of Johnson's equation.)

In other words, the two equations do *not* predict the same quantity
and they are *not* supposed to be the same equations. As I said before,
Dr. Best made a lot of conceptual errors but his equations seem to be
valid. If you break Johnson's equation into two parts representing E+
and E-, the E+ part will be Dr. Best's Eq 6.

Please consider the following matched system with a 1/2 second long lossless
transmission line. The physical rho is 0.5. Assume VF1 is a constant 70.7V.

100W XMTR---50 ohm line---x---1/2 second long lossless 150 ohm line---50 ohm load
VF1=70.7V--> VF2-->
<--VR1 <--VR2

V1 is equal to 70.7(1.5) = 106.06V and is a constant value
V2 starts out at zero and builds up to 35.35V
VF2=V1+V2 assuming they are in phase

Here is (conceptually simplified) how VF2 builds up to its steady-state value.
VR2(t+1) is 1/2 of VF2(t) and V2(t+1) is 1/4 of VF2(t)

Time in
Seconds V1 VR2 V2 VF2
0 106.06 0 0 106.06
1 106.06 53.03 26.5 132.56
2 106.06 66.26 33.13 139.19
3 106.06 69.58 34.79 140.85
4 106.06 70.4 35.2 141.26

5 106.06 70.63 35.32 141.38
6 106.06 70.69 35.34 141.39
7 106.06 70.7 35.35 141.4 very close to steady-state

My rounding is a little off but above is a close approximation to what happens.
Note that VF2 is equal to V1 + V2 and converges on the proper value of 141.4V.

Steady-state VF2 = 106.06 + 26.5 + 6.63 + 1.66 + 0.41 + ...
This is indeed of the form 106.06(1 + 1/4 + 1/16 + 1/64 + 1/256 + ...)
or VF2 = V1(1 + A + A^2 + A^3 + A^4 + ...)

Patent pending means the same as patent applied for.
No guarantee that it will ever issue. At least that's the
usage by the patent attorneys I work with.

What you are thinking of is the period of time between
when the examiner allows one or more claims and the
actual issuing (ie printing) of the patent. I recently had one of my
patents get issued by the USPTO, but the examiner had allowed all the claims
last fall. In that case, it was essentially a done deal when
the claims were allowed.

Also, it is now the case that after 18 months, patent applications
are public. You should be able to read Fluid Motion's steppir patent
applications by now.

Don't forget that it is possible that some patents have issued but
the very overworked staff at Fluidmotion hasn't gotten around to
updating the sales literature. I currently have over a dozen patent
applications in process at the USPTO and it gets hard to keep track of them
all, even with the help of our legal department.

IMHO, I don't see how they can patent the basic concept of
the SteppIR, but then I'm not a patent attorney. There
is the "Cliff Dweller" adjustable dipole as prior art, but will
the examiner ever find that. Maybe they are just patenting the idea of
the tape in the hollow tube.

I don't know if this has been mentioned before or not. There is
another problem other than interference. It's an IMPORTANT and
perhaps fatal drawback.

If a line or two goes down, not only do you lose power, but also the
means to communicate. Emergency messages will NOT get through to
anyone connected via this setup. They will STILL need regular
broadcast signals via radio or television.

In the worst case scenario, you'd lose email, phone, radio AND tv
all at once. With converging technologies, this is altogether too
likely.

Will the government carry the burden of responsibilty should someone
be killed or hurt because of this 'broadband initiative'?

I do not have a United States address, so I can not send this
suggestion myself. Please distribute this concern also. I hope it
will be noticed by the communications commitee.

>> If you value radio, this may be the last and only chance to have your
>> voice heard to stop BPL from destroying your hobby. The FCC has extended
>> the comment period for BPL.
>>

Kindly understand that not everyone is convinced that BPL will 'destroy' ham radio or SWL'ing. I am one of many that disagree with your assessment, and agree with the prevailing position that BPL is an important technology option that can co-exist with the 'ham' community, for example.

Ham radio is not licensed as a hobby; it is licensed as a service. When 'hams' atempt to prevent adoption of new technologies, rather than foster them, then there are those who debate the value of our spectrum allottments.

Working together with BPL is the best course for ham radio. This will allow the marketplace to decide if BPL is a viable option, rather than putting the focus on ham radio as a passe and reactionary group--which is the public perception in the popular press at this time (for example, the recent WSJ front page article).

Think about these comments in the context of what has happened so far with BPL. Then project the most likely scenario moving forward.

Sorry to spoil your fun, Cecil, but 141.4 v is not the forward voltage, it's the max voltage of the standing wave. This is the same mistake that Steve made. I asked you to rethink what the forward voltage and you have come up wrong.

You are using circuit theory for superposition, as Steve did, when circuit theory fails to apply in certain transmission line cases. This is one of those cases. In circuit theory you can superpose the voltages from two sources and V1 + V2 equals Vtotal. But the re-reflected voltage CANNOT be added to the source voltage in the transmission line case to obtain Vfwd, because there is only ONE source.

I'll say it again, Cecil, V1 + V2 = maxV of the standing wave--V1 + V2 does NOT equal Vfwd because V2 is not a second source, it came fr om ONE source, the transceiver, and therefore superposition of V1 and V2 does not apply to establish Vfwd.

Therefore, it is true that maxV may be incident on the load if the relative phase between the reflected and forward waves permits, The only time the forward wave is incident on the load is when the load = Zo.

Please, Cecil, go back to the drawing board and come up with the correct Vfwd--it is not equal in any way to the right-hand side of Johnson's Eq 4.23;. Remember, I said earlier that when rho = 0.5 and the circuit is matched, Vfwd = Vsource x 1.1547. When you discover where the 1.1547 came from when rho = 0.5 you will have discovered the source of Vfwd.

>Steady-state VF2 = 106.06 + 26.5 + 6.63 + 1.66 + 0.41 + ...
>This is indeed of the form 106.06(1 + 1/4 + 1/16 + 1/64 + 1/256 + ...)
>or VF2 = V1(1 + A + A^2 + A^3 + A^4 + ...)

Wrong, Cecil. Change VF2 to 'E', the max value of the standing wave, and the values obtained from the sum of the terms in the geometric series will be correct.

I'll make it a little easier for you, Cecil. I' ll give you two ways to
determine Vfwd.

Way 1. Vfwd = sqrt(Power fwd x Zo)

Way 2. Vfwd = Vsource x sqrt[1/(1- rho^2)]

Now plug rho = 0.5 into the expression for Way 2 and see what comes up.

Cecil, let's take it one step further and include current, forward current, that is, Ifwd.

Ifwd = Isouce x sqrt[1/(1 - rho^2)]

Now let's see what happens with a souce voltage of 70.71 v at 100 w on a 50-ohm line. The source current is 1.414 a.

Now find Ifwd x Vfwd and see what comes up.

> Sorry to spoil your fun, Cecil, but 141.4 v is not the forward voltage, it's the
> max voltage of the standing wave. This is the same mistake that Steve made. I
> asked you to rethink what the forward voltage and you have come up wrong.

Nope, I haven't, Walt. The maximum voltage of the standing wave equals the maximum forward voltage plus the maximum reflected voltage. The forward voltage is 141.4V. The reflected voltage is 70.7V. The maximum standing-wave voltage is 141.4V + 70.7V = 212.1V. The minimum standing-wave voltage is 141.4V - 70.7V = 70.7V. The VSWR = 212.1V/70.7V = 3:1. Rho = 0.5 SWR = (1+Rho)/(1-Rho) = 1.5/0.5 = 3:1 Everything is perfectly consistent.

So the maximum standing-wave voltage is 212.1V, not 141.4V.

Please reconsider - here's the steady-state powers for the above matched example:

100W XMTR-----50 ohm line---x---150 ohm line---50 ohm load
PF1=100W--> PF2=133.33W-->
<--PR1=0 <--PR2=33.33W

The forward power is 133.33W and Z0=150 ohms. Last time I looked, the square root of [133.33W(150 ohms)] was 141.4V.

141.4V^2/150 ohms equals 133.33W. The forward voltage is indeed 141.4V.

Until you discover your mental block, whatever it is, this discussion is not going to progress. The above example is exceptionally simple so your mistake must also be simple. You, yourself, have used the above example and always agreed that 100W + 33.33W = 133.33W, i.e. forward power equals generated power plus reflected power.

This is a great thread, I have a question about your post. If the all
the reflected energy is reflected back toward the load, is it in phase
with the original or subsequent energy? or does it matter?

OK, here's the example:

100W XMTR---50 ohm line---x----1/2WL 150 ohm line---50 ohm load
PF1=100W--> PF2=133.33W-->
<--PR1=0W <--PR2=33.33W

> Way 1. Vfwd = sqrt(Power fwd x Zo)

So Vfwd = sqrt(133.33W x 150ohms) = 141.4 volts (that's what I said)

> Way 2. Vfwd = Vsource x sqrt[1/(1- rho^2)]
> Now plug rho = 0.5 into the expression for Way 2 and see what comes up.

OK, Vfwd = 70.7V x sqrt[1/0.75] = 81.6 volts (something wrong there)
We know Vfwd has to be 141.4V as calculated above using Ohm's law.

Walt, your two ways don't yield the same value. Perhaps that is the
source of your confusion about what Dr. Best said. Your Way 2 appears
to be a calculation of the voltage delivered to a mismatched load.

This equation for voltage was wrong. Perhaps, we should resolve that
problem first.

Forward current can be calculated from the square root of (forward
power divided by Z0). So IF2 = SQRT(133.33W/150ohms) = 0.943 amps

Funny thing is that 141.4v*0.943a = 133.33 watts, the known forward
power on the 150 ohm line.

I am from the old school, Ken. I believe that power is a scalar and
doesn't possess phase. IMO, any phase calculation that you see being
used on power originates from the voltage phase and/or current phase
associated with that power. It is done all the time in optics.

The answer to your question is, assuming PA stands for Phase Angle:
Since forward voltages and forward currents are in phase, V*I*cos(PA)
yields watts with no vars. Since reflected voltage and reflected current
are 180 degrees out of phase, V*I*cos(PA) yields watts with no vars.
So extremely loosely speaking, the "phase" of the power can be considered
to be the same as the phase of the voltage or current since they are
the same phase. However, such a consideration cannot be considered to
be good physics.

Walter, W2DU wrote:
"I`ll give you two ways to determine Vfwd."

Walter makes it too easy by using the power relationships, but that`s the way it is. The forward (incident) wave is opposed by Ro in a practical line. The reward (reflected) wave is also opposed by Ro (the surge impedance) of the line.

Power from the transmitter is nearly the same as that delivered to the load as loss is small and no significant room exists in the line to store RF.

Power to the load is the difference between forward power and reflected power.

The voltage at any point on a mismatched line is the sum of the forward and reflected waves at that point but is merely a manifestatoion of SWR and has little practical value. At a current or a voltage loop (maximum), the forward and reflected amps or volts are in-phase. So, if a line is opened at a loop point, the impedance looking toward the load is a pure resistance regardless of the nature of the load (see page 37 of "Transmission Lines, Antennas, and Wave Guides" by King, Mimno, and Wing).

Best regards, Richard Harrison, KB5WZI

>Shortwave, VHF, UHF. Military comms, utilities, ect. You do actually
>participate in the radio hobby, don't you?

No. I do not consider 'radio' a hobby. I appreciate the fact that others do.

Amateur radio is a service, for example.

I clearly do not understand that eavesdropping on the marine band with a unidirectional antenna is a hobby. I invite Richard to expound its virtues; tell us who does it; tell us how such hobbyists meet; discuss their fun info; and so on.

This is a new one, relatively, to me.

BTW, I have been a ham since 1966; have won various contests; have DXCC honor Rolls; 8BDXCC (equivalent); #1 DXCC Honor Roll; and so on.

I have also done various public service stuff as a ham, BTW.

I've been around the pike, so to speak.

All true and completely irrelevant to Dr. Best's article since he was
never talking about the net voltage. He is talking about the forward
voltage. Any notion that Dr. Best was talking about net voltage is a
mistaken notion. (I can't believe I'm defending Dr. Best but he said
what he said.)

Re: BPL - impact on radio communications
As tests and any sort of technical common sense would make obvious, broadband transmissions on miles of unshielded power lines will create havoc with the reception of micro-volt level radio communication signals. The concept is pure nonsense to anyone with a technical background. My BSEE (with communications specialization) and top FCC commercial and amateur radio licenses does not make me a great expert, but anyone with a comprehension of radio transmission and reception knows that the BPL concept does not work, unless basic MF & HF radio is sacrificed. BPL is a poorly thought out concept, with the unlikely potential for profit driving this otherwise unfathomable concept. Please get some honest technical input before allowing this BPL debacle to continue.
Sincerely, AK

>to be a calculation of the voltage delivered to a mismatched load.

Cecil, you've hit the problem on the nose. Until a few posts past I didn't realize you were using a 150-ohm line. I've been using 50 ohms for the line Zo terminated with 150 ohms, and you'll find my numbers are correct for that Zo. Vfwd = 81.6 v is correct for 100 w on a matched 50 ohm line with 3:1 mismatched load. You'll also get 81.6 using my Way 1.

However, on a 50-ohm line with a 3:1 mismatch and Vfwd = 81.6v (actually it's 81.65 v), the reflected wave is 40.83 v. When the system is matched the phase of the re-reflected wave is 0ï¿½ and is also 40.83 v. Therefore, V1 = 81.65 v and V2 = 40.83,v, which means V1 + V2 cannot equal Vfwd. Yet, in the paragraph preceding Steve's Eq 13 he says that when the phase is 0ï¿½ Eq. 13 derives PFtotal. It does not.

Using his Eq 7 V1 yields P1 = 133.33 w, and using his Eq 8 V2 P2 = = 33.33 w. Using these values of P1 and P2 in his Eq. 12 yields PFtotal = 238 watts, which is also what we get when plugging V1 and V2 into his Eq 9. We know 238 watts is incorrect, because it need to be 133.33 w. It makes no sense to plug P1 from Eq 7 into Eq 12 to find PFtotal, because P1 is already PF total.

This clearly proves that Eq 12 is invalid, because Eq 7 and 8 are valid.

I am studying your case with the 150-ohm line, but I haven't yet corralled it.

Walt

re-reflected voltage is also 40.83 v.

Thanks, Richard, what you say is true, but problem is in determining the method to find the forward voltage when the line is mismatched.

Walt

>generated power plus reflected power.

I assure you, Cecil, there is no mental block.

Returning to Steve's paper, and as I said in the preceding post, Steve precedes his Eq 13 stating this equation works under the conditions where V1 and V2 are in phase. This means that the system is matched and thus the re-reflected voltage equals the reflected voltage. With forward voltage V1 = 141.4 and reflected voltage V2 = 70.71, and using these values in his Eqs 7 and 8 and then plugging the resulting values of P1 and P2 in Eq 13, we get PFtotal = 300 w. This again proves that Eq 13 is invalid, because P1 from Eq 7 already derived the total forward power, yet he uses P2 in Eq 13 to obtain the total forward power.

Do you not see what's wrong here?

Walt

Before cell phones were widely available, the phone company around here
(Belmont, CA)
had a phone patch service for marine vhf. I met at least one guy who had a hand
held
marine vhf radio which he used to carry around so he could make phone
calls without having to find a pay phone. I expect monitoring the marine band
could get pretty boring, and might get you a charter membership in the
dull men's club, but little else. Of course, if you own a boat that's another
story.

Nice letter, but it will fall on deaf ears -- FCC head Michael Powell
is a cheerleader for BPL.

My suggestion: vote for John Kerry on Nov. 2nd. Kerry does not like
Powell. Powell will be out. And we can start afresh with a new FCC
head, one who might worry more about the consequences of BPL than this
business-friendly administration ever will.

I've only explained and presented it about ten times now.

The impedances are irrelevant, Walt. The equations have to
work no matter what the impedances.

I have presented ASCII schematics of what I was discussing.
Would you be so kind as to do likewise? I am getting sick
and tired of this run-around.

Not the pike that several thousand hobbyists enjoy, perhaps most of whom are
licenced amateurs!

Try http://www.wunclub.com/ and really dig around, you'll find that marine
listening is a close second only to military aircraft monitoring, maybe
commercial aircraft after that.

IF the claims about BPL were accurate, it would have such a profound effect
on so many major forms of government and commercial communications, that the
BPL lifespan might be about a week after full scale exposure. So like
yourself, I am watching with open eyes and ears for more tests to prove it's
a boon or a bane.

No! NO! NO! The voltage re-reflected from any physical impedance discontinuity equals the reflected voltage times the physical reflection coefficient. That is the S-parameter term s22(a2). s22 is the physical reflection coefficient. a2 is the reflected voltage incident upon port 2.

If the reflected voltage is 70.7V and the physical voltage reflection coefficient is 0.5, then the re-reflected voltage is 35.35V. This is all explained in HP's AN 95-1 on S-parameter analysis.

That's my anecdotal sense as well, Tom. Hence my natural curiousity as to why someone with an apparent sense of advanced skills would consider this worthwhile, and exhort us to 'benefit a service'. I would still like to 'get it'. I am open to it. I am puzzled why I am not getting an answer from the person who started this thread.

Kindly fill us in, Richard. We're friendly.

The licensed amateur part doesn't sound right, but your link is very helpful.

Wouldn't it make more sense to make construction info available on an
appropriate site to those who are more likely to see it? Perhaps a newsletter?
Trade pub ? Monitoring Times?

This request seems to have come out of no where, with no context. It has the
appearance of a bait, but that's a personal opinion.

Play devil's advocate: how do we, as 'hams' convince others that increased QRM and QRN --prevents-- our use of licensed privileges.

To wit: consider HF mobile. Why should anyone care if a roving 'ham' gets blasted by QRM when driving underneath a power line? The emergency comm argument has limited viability: most emergency comm happens at VHF or UHF these days, especially mobile.

Provide a compelling answer and you've certainly made it difficult to justify BPL. Don't make a case and you've thrown the focus on the necessity of certain HF 'ham' activities in a broader context.

Hope this helps.

Cecil, when a mismatched line is matched at the input with a tuner the
reflection coefficient at the matching point in the tuner is 1.0 when the tuner
is matched, thus the re-reflected voltage wave must be equal to that of the
reflected wave. My statements are all based in these conditions.

These conditions are in effect when using an antenna tuner, so any equations
that work in general must work with the tuner setup. When the tuner is matched
the re-reflected voltage is in phase with the source wave. Then, according to
the conditions Steve set forth to use Eq 13 this equation should be viable for
use with conditions set up with the tuner, but it doesn't. You say this equation
is valid, so can you come up with the correct answers using it with a tuner
matching the mismatched line?

Unfortunately, my S-parameter texts are behind in Florida, and I've forgotten
the significance of the 'a' and 'b' terms.

Unfortunately the folks at the FCC that are pushing BPL have zero comprehension of radio transmission or reception, in fact have zero comprehension of anything technical. They are a bunch of lawyers who only comprehend money. Chairman Powell wouldn't know a transistor from a doorknob, I doubt he can turn on a tv without help. He will probably leave the FCC after BPL gets rolling for some cushy outrageous paying position at some BPL intenty as his reward for helping to push this debacle down everyone's throats.

Sadly, I am aware of that. Either he's been paid off, or the people pulling his strings have been paid off by the power company special interest reps. My "but anyone with a comprehension of radio transmission and reception knows that the BPL concept does not work" and "unfathomable concept" comments were certainly directed Powell's way. Oh for the good ol' days when at least one or two of the FCC Commissioners were ex-FCC field engineers who understood something about the medium they were supposed to be in charge of.

That is NOT true of an S-parameter analysis, Walt, which is essentially what Dr. Best is using in his article. In a system with reflections the S-parameter reflection coefficients are NEVER equal to 1.0. How can I make you understand that you and Dr. Best are using entirely different systems of analysis and yours has no bearing on his.

Here's your arguments:

Steve: "It's a plant."

Walt: "No, it's a tree."

Steve: "No, no, it's a plant."

Walt: "No, no, it's a tree."

In the following matched system, the reflection coefficient in Dr. Best's system of analysis is ALWAYS |0.5| and is NEVER 1.0. This is also true for an S-parameter analysis. The only difference between Dr. Best's analysis and an S-parameter analysis is that he didn't normalize his voltages to SQRT(Z0). I presented that fact a couple of postings ago.

100W XMTR---50 ohm line---x---1/2WL 150 ohm line---50 ohm load.

Nowhere at no time is Dr. Best's reflection coefficient equal to anything except |0.5|. It is an absolute constant whether the XMTR is off, in the transient state, or in the steady-state. Please read this paragraph over and over until it soaks in. In Dr. Best's system of analysis, the only time that the reflection coefficient is 1.0 is in a system with a short, open, or pure reactance. In his system of analysis, a reflection coefficient of 1.0 NEVER occurs at a matched or mismatched impedance discontinuity if the impedances are not zero or infinite (or purely reactive).

> Unfortunately, my S-parameter texts are behind in Florida, and I've forgotten
> the significance of the 'a' and 'b' terms.

The HP AN 95-1 ap note is available at:

http://www.sss-mag.com/pdf/hpan95-1.pdf

The S-parameter reflection coefficients are constant and do NOT change as the reflected power changes. They are the same with no signal applied, or during

the transient state, or during the steady-state. The S-parameter reflection coefficient is *NEVER* 1.0 when there exists an impedance discontinuity.

You and Dr. Best are NOT USING THE SAME REFLECTION COEFFICIENTS!!!!
You and Dr. Best are NOT USING THE SAME SYSTEM OF ANALYSIS!!!!
Nothing you say about your system of analysis is relevant to the system of analysis that Dr. Best used.

My degree is in Power Engineering and I learned the above at
Texas A&M. Of course, Volt-Amps have a phase, but power always
lies along the real axis. What would be the physical meaning of
25 watts at 45 degrees?

Cecil, Steve's equations are out there for all to see as general equations. Nowhere has he made any caviats to the contrary, or that they only work for reflection coefficients of 0.5. If they only work for one specific coefficient it should be so noted that they are not for general use. And if equations are not valid for general use they are then invalid.

Can you explain this?

Walt

>
> Can you explain this?

They do work for any reflection coefficient, Walt. He chose 0.5 for
his examples because a 0.5 voltage reflection coefficient reflects
half of the voltage and that's easy to do in your head. The S-parameter
analysis will work for any reflection coefficient.

If you will take the time to perform an S-parameter analysis, you
will understand Steve's equations. His analysis is completely
different from yours.

Here's one with a voltage reflection coefficient of 0.707. You
can pick any Z0 for the 1/2WL line below and therefore choose
any reflection coefficient you want.

100W XMTR---50 ohm line---x---1/2WL 291.5 ohm line---50 ohm load
VF1=70.7V--> VF2=241.45V-->
<--VR1=0V <--VR2=170.7V

Dr. Best's V1 = VF1(1+rho) = 70.7(1.707) = 120.7V

Dr. Best's V2 = VR2(rho) = 170.7(0.707) = 120.7V

VF2 = V1 + V2 = 120.7V + 120.7V = 241.4V (200W forward)

This is just an S-parameter analysis without normalizing to the
square root of Z0. In fact, we can *derive* Dr. Best's equations
from the S-parameter equations simply by multiplying by the
square root of Z0.

b2 = s21(a1) + s22(a2)

b2*Sqrt(Z0) = s21(a1)Sqrt(Z0) + s22(a2)Sqrt(Z0)

VF2 = b2*Sqrt(Z0), V1 = s21(a1)Sqrt(Z0), V2 = s22(a2)Sqrt(Z0)

VF2 = V1 + V2

Source record: 93732

Cecil, how about doing me a favor and humor me a little.

How about solving my example, the one that Steve took from Reflections and then trashed. To repeat, 100 w, 70.71 v source, 50-ohm lossline terminated in a 3:1 mismatch and perfectly matched at the input with a rho = 1.0.

Vfwd = 81.65 v and Vref = 40.83 V. Please solve this using Steve's method of solution, Eqs 5 thru 13.

If this problem can't be solved with Steve's method, his method must be invalid, not general.

Walt

Unfortunately, everybody knows that BPL will hinder HF. There is no argument here as all testing shows this. The question is really how much is acceptable. 5db/m increase in noise floor at 500M nor 9uV/m at 10M of interference is not acceptably to me on any HF freq. Goodbye QRP, especially if you live in the sticks! You may never hear distant shortwave broadcast again unless you live miles from a powerline.

Testing in the united states has not been truthful, utilizing Shoody test techniques and deception. They even picked a test community with underground power lines and no nearby amateurs. I'm willing to bet that all the people are on cable/DBS TV and nobody had a shortwave radio.

BPL is bad and the FCC knows it. So does FEMA, the military and the coastguard. That is why they have provisions in the regulations for them (and them only) to restrict BPL away from their facilities. Hams will not have this protection. Both the British and Germans pulled BPL when field test revealed the true nature of the interference.

Why wait until it's too late to do anything about. If you wait, you lose. The WSJ (Wall Street Journal)is there to promote business. BPL is business and amateur radio is not. I will let others painfully expand about these politics on many vectors. ;-)

Please, if you value radio, it only takes a few minutes to fill out a FCC comment.... better safe than sorry.

Glad you did something on this! I sent mine in (added to yours some);

I recommend that the FCC ask for a technical showing that BPL will
not interfere with other existing communications in these bands
before establishing Rules and Regulations. I also recommend that
the FCC ask for a technical showing signal losses (of BPL) on
distribution grids in a city. These losses are substantial, and can
indicate that BPL works in only very limited cases, making it
basically unusable in urban and suburban areas.

Existing Emergency communications will be hindered to levels
directly responsible for the loss of life, because of a raised
noise floor or excessive leakage in various locations.

There are many technologies that make BPL unnecessary. BPL will
never be able to carry the high bandwidth demands for mass
distribution of video much less the up-and-coming HDTV.

Please do not destroy the foundation of radio communications below
50 MHz for a unproven technology that is suspected of causing
widespread interference.

In Writing, I wish to persuade the FCC from allowing BPL to be
implemented. The destruction or at the least, deterioration of the
shortwave bands is not only a violation of ITU laws that protect
international broadcasters from interference and jamming, it will
be destroying many people's life hobby. Amateur radio will be
reduced to users with high-power amplifiers and large antennas.

Thank you.

> mismatch and perfectly matched at the input with a rho = 1.0.

Here's the configuration.

100W XMTR--50 ohm line--x-tuner-y--1wl 50 ohm line---150 ohm load

The tuner function is replaced by a 1/4WL series section which
performs *exactly* the same function so we can see what is really
happening inside the tuner. The match point is at 'x', not at 'y'.
The system is NOT matched at 'y'. Therefore, Dr. Best's system is
not matched at the output of the tuner. His choice to use a tuner
for that illustration, instead of a 1/4WL transformer, was a very
bad one and has obviously led to a lot of confusion and misunderstanding.

rho=0.268 rho=-0.268 rho=0.5
100W XMTR---50 ohm line---x---1/4WL 86.6 ohm line--y--1wl 50 ohm line---150 ohm load
VF1=70.7V--> VF2=96.58V--> VF3=81.65V-->
<--VR1=0V <--VR2=25.9V <--VR3=40.82V
PF1=100W--> PF2=107.76W--> PF3=133.33W-->
<--PR1=0W <--PR2=7.76W <--PR3=33.33W

The mismatched impedance discontinuity at 'y' is interesting because
we have forward power and reflected power flowing to/from both directions.
That's what happens at a tuner output. The actual match point is at the
tuner input at 'x'.

At point 'y' on the 50 ohm line we have a V1y of 70.7V corresponding to
the 100W forward power that made it through the impedance discontinuity.
This can also be calculated by using the transmission coefficient. Since
the impedance is a step-down impedance, tau = 1-rho

V1y = VF2(1-rho) = 96.58(0.732) = 70.7V

V2y will be VR3(rho) = 40.82(0.268) = 10.94V

VF3 = 70.7V + 10.94V = 81.65V. (133.33W)

The modified S-parameter analysis works once again and this time it
is at an unmatched impedance discontinuity at point 'y'.

We could also do the modified S-parameter analysis at point 'x'.

V1x = VF1(1+rho) = 70.7V(1.268) = 89.6V

V2x = VR2(rho) = 25.9V(0.268) = 6.94V

VF2 = V1 + V2 = 89.64V + 6.94V = 96.58V (107.7W)

Chip -

I respectfully suggest you think again about emergency comm's...
this time slightly outside the most literal "box."

Amateur radio already suffers from an aging base of licensees, and
recruiting new ones is difficult. A very high percentage of the "fun"
involved in amateur radio is HF operation. Providing VHF/UHF
emergency comm's is more like work... our payback for spectrum use.

If the Government says "To Hell with amateur radio--use their HF
spectrum for flaky and redundant ISP service," then many amateurs
will quit--AND leave their VHF/UHF emergency service as well.
I'm likely to be one of them.

And what would the recruiting line be then? "Become an Amateur
Radio operator, and you can spend your time working bicycle
races, and hope to get a cross-town emergency gig some day?"
Whoop-de-do, what fun!

I doubt the FCC will have to hire more staff to process Amateur
applications, with exciting prospects like that driving what's left
of the hobby.

Well, sort of.
I want to broadcast an FM radio signal playing MP3 files in a variety of buildings from single story homes to multistoried buildings.
Small dwellings are no problems but the larger ones present a problem. The location of the broadcast unit may be mandated by factors beyond my control. The power needed to reach the opposite corner might be to high.
Is there any way to use internal wiring as a short range antenna that would be limited to the building for all practical purposes.

Another possible solution that I can't find an answer to would be to put the signal on an unused TV channel if the building is wired for cable.

I've done a lot of Google searching but can't find anything specific.

Thanks.

Source record: 93743

I had a thought the other night. My wireless keyboard has limited range when my Home Theater PC (HTPC) is enclosed in a cabinet. I have already tapped into the keyboard receiver to access the antenna trace on the circuit board by adding a long wire which I string away and outside of the cabinet. This improved the range. Then I had my thought, what about wiring my external antenna wire into the ground of a 3-prong power outlet. I thought about testing the voltage and current between the antenna wire and ground prong but decided what the heck it is suppose to be grounded. Well, the range is well extended now, but I am wondering what are the risks? I am probably risking damage to my keyboard receiver but so far it works great. I am a very amateur electronics person so I know some stuff but I don't know what would be the best solution to protecting the receiver from damage, if it is needed at all. My questions are why shouldn't I do this, what are the risks, and is there anyway to do this while minimizing the risks?

Also, what about 802.11b? I am thinking that is even more risky since the AP is both a receiver and transmitter and grounding the transmitter signal would probably diminish its range substantially.

Thanks!

Hi Michael

Well it isnt something I'd ever do to 2.4GHz signals. <grin>

Given the frequecy in use there is going to be pretty severe attenuation in any length of open wire so the fact that the ground wire is "grounded" is probably superfluous. I do know however that there are warnings on WiFi equipment about interference from fluro's and other electrical equipment in close proximity so I'd guess that with those kind of induced voltages on the RX antenna it could in fact work not as well.

Would the voltages hanging around the earth line as noise be damaging to the WiFI RX? I'd say yes but it would depend on the protection (if any) at the RX front end. Obviously depends on what electrically noisy things you also have connected to the mains and how much output there is on 2.4GHz.A hard call, sorry!

If I was trying to increase the range I'd build a antenna inside a tin can of the receiving unit "pointed" in the direction where I would sit with the keyboard. The keyboard I would also modify so that it had at least a half wavelength dipole on the outside of its case on the top/far edge.

There are lots of 2.4GHz antenna building ideas on the internet.. Go for it!

802.11b? I'd stick to purpose built antennas, Home made or commercial.

Cheers Bob VK2YQA

Not to my knowledge, Jan.

The presently and easily available (that is, free) info on fractal antennas for hams is poor in content and often factually inaccurate, in my opinion, and this is likely to remain so. In the world we live in today, this makes a lot of a sense in its own quirky fashion.

Commercial uses are a different story, however. Of course, that's not what this NG is about.

When hams switch to software radios in a big way then fractal antennas targeted to hams might be worth making more widely known. With some luck, they'll be a few of us 'hams' left then!

Hi,

Almost all the fcc commissioners, Mr. Powell included, have legal backgrounds,
experience writing legislation for communciations industry (lobbyists ??)
special interests and working for members in congress.

Three of the comm. have received degrees from universities in
north carolina.

You are correct, it is about the money.

They tried this back in the late 1970's here in ny,
they wanted to eliminate the meter readers to save money
but that did not work out.

Don't know why they want to use the hf regions, why not 10 gig ?

Plus, dsl just dropped the price here another $ 5.00 per month to
be less expensive the the cable co. road runner net.

I don't have a tech degree or work in rf but the harmonics
over miles of cable and the expense of these repeaters and or filters
seems too expensive to turn a profit in rural areas that bpl was pushing for.

BTW, one city in MD has parted ways with their bpl partner and is looking
for another one, after spending lots of money to wire up their city.

hi mike,

How much output power are you planning on using ?

One thing to watch out for is if these mp3 files are of
copyrighted work, you may have to pay to broadcast
these files.

You could try using two antenna, each cut for the FM
frequency you want to use. Connect them with a long
section of good coax, you just built a passive repeater.

Locate one antenna outside the building and the other
inside and thay could work for some or all building.

Why do you think Kerry thinks any different than Bush on BPL? Bush has already gone on record as being "pro-choice" on BPL. Has Kerry staked out the opposite side of the issue?

Which politician, of either party, is against BPL? Which FCC commissioner, of either party, is against BPL?

Great. If BPL is unworkable, let it fail in the marketplace. Do you really think any politician will vote to preempt a failure? Let's say politician A blocks BPL. Politician B says "Mr. A wants to restrict your freedom to choose! I say every American has the God given right to pick which ever high speed internet access plan he can get!!" Then sleazeball campaigner B starts a whispering campaign -- "Who's pocket is A in? The phone company's? The cable company's? The satellite company's? All of them? Well, there must be some reason he wants to restrict your freedom!!" The upcoming election might be close, and nobody is going to restrict "Freedom" this year.

Note that I used the non-partisan terms A and B to describe the politicians. I know there people around who think one party or another is the Repository of Morality and the other is the Heart of Evil, but I ain't one of 'em.

Which Commissioner do we split in half?<grin>

There are five Commissioners. No more than three may be members of the same party.

http://www.fcc.gov/aboutus.html

Unfortunately I wouldn't count on a Democratic Presidency stopping BPL. Firstly, they're just as susceptible to campaign contributions as Republicans. Secondly, the GOP Congress has a record of overturning FCC decisions if they offend enough lobbyists. (witness the anti-LPFM legislation - which was enacted despite a Democratic President who opposed it)

Democratic Congresses in my lifetime never had a record of trying anything that blatant. Doesn't mean they haven't learned from the GOP since then.

Hi Michael, you are correct there is no voltage on your home ground wiring under normal conditions. And there is normally no more noise on ground than is also present on the line and neutral wiring. But, if you are in an area prone to thunderstorms, or if there are equipments in your home capable of generating surge currents, AND you use standard MOV-type surge protecting "power strips" there is a risk. Any transisent surge voltages on your circuits could be referenced to ground by those surge protectors and right into your receiver's front end.

> Also, what about 802.11b? I am thinking that is even more risky since
> the AP is both a receiver and transmitter and grounding the

It could also cause harmful interference to other equipment including it's own receiver.

That's one of those nonsense comments that sounds good, but doesn't work. Once "the marketplace" gets tested, amateur radio and most of the other users of HF and MF radio reception will be out of business - never to bounce back once destroyed. Meanwhile, BPL will be "workable" for those areas that never had good cable access and where people were too cheap to use satellite or telephone alternatives. BPL isn't "unworkable" - it's the "unreasonable" sacrifices that must be made to allow nationwide radio spectrum disruption for some trivial gain to a few people and a few big businesses.

You must be that same guy that thought he had a God given right to dump whatever he wanted into the Nashua river when I lived along it. His

corporate garbage killed all the fish and stunk-up the river for the rest of the world, but using the river for his personal dumping ground was his "right"! Some good ol' New England Yankee took on this "my-rights-over-everyone-else" guy by paying a cement truck to dump a full load of concrete in the guy's drainage canal to the river. The sheriff was called, saw what was done, heard why it was done, and went home without issuing any citation. Too bad that a load of concrete won't stop BPL.

>
> V2y will be VR3(rho) = 40.82(0.268) = 10.94V (2.39W)
>
> VF3 = 70.7V + 10.94V = 81.65V. (133.33W)

The power equation at point 'y' looking toward the load is:

PF3 - P1y - P2y = constructive interference

Note that P2y + constructive interference = re-reflected power.

133.33W - 100W - 2.39W = +30.94W

A '+' sign on the interference term indicates constructive
interference.

There is 30.49 watts of constructive interference at 'y' looking
toward the load. That energy must come from somewhere.

Therefore, there is 30.49 watts of destructive interference at
'y' looking toward the source. The flow of energy from the
destructive interference event to the constructive interference
event is an interference-caused reflection.

The total re-reflected power at 'y' is 2.39W + 30.94W = 33.33W
In this case, everything except P1y is re-reflected. This is in
agreement with Walter Maxwell and in disagreement with Dr. Best.

> V1x = VF1(1+rho) = 70.7V(1.268) = 89.6V (88.09W)
>
> V2x = VR2(rho) = 25.9V(0.268) = 6.94V (0.556W)
>
> VF2 = V1 + V2 = 89.64V + 6.94V = 96.58V (107.7W)

The power equation at point 'x' looking toward the load is:

PF2 - P1 - P2 = constructive interference

107.7W - 88.09W - 0.556W = +18.42W

The '+' sign tells us that there is 18.42 watts of constructive
interference at 'x' looking toward the load. That energy must
come from somewhere.

Therefore, there is 18.42 watts of destructive interference at
'x' looking toward the source. This is also an interference
reflection.

The total re-reflected power at 'x' is 0.556W + 18.42W = 18.98W
Everything except P1 is re-reflected at a match point.

Using the S-parameter equations:

b1 = s11(a1) + s12(a2)

b2 = s21(a1) + s22(a2)

s21(a1) is the only voltage term that doesn't get reflected
at least once.

s11(a1), s12(a2), and s22(a2) are all reflected terms. If the
energy in these terms winds up at the load, they have all been
re-reflected.

Hi Chip, yes there are websites, monitoring lists and circulars that specialize in utility listening. The WUN is just the biggest, not the only by any means. It has been my experience in the last 12 years of that part of the hobby, that about 90% of the "members" are anonymous non-posters. When the mailing addresses of list members were once public, they included almost every government agency. Monitoring marine safety on VHF and HF by hobbyists has definite public safety benefits very similar to licensed amateur groups such as the Maritime Mobile Net that works 14.300 mHz. The post may have been bait, and most of us would have chosen a little different form of explanation of what/where/why, etc. But there are very few affordable antennas manufactured for the bands commonly referred to as "Utility" (non-ham bands), and this is a logical place to ask for help in that area.

Can someone please comment on the following statements and questions?
Thanks.

1 The reflector and director element lengths and spacings of Table 1 are good for a yagis where d/lambda is 0.0085 and boom is non conducting.

2 You make a correction to the lengths when d/lambda of your reflector and director element diameters are other than 0.0085.

3 When you use a metallic boom, you have to make corrections to the element lengths as per Table 10.

4 I take it that whatever you put in place for DE, all spacing and reflector and director elements continue to remain correct. So you can place whatever you want for DE, hertz dipole, folded dipole, gamma match, T match, DE with 1/"4 dia tube or 1.2" dia tube -it does not matter, parasitic element lengths once calculated need not be changed whatever you DE you place in the design. Spacing always remain the same.

5 How do you go about designing for DE?

6 Do the element length corrections due to use of a metalic boom assume a particular element fixing method? Such as through the boom or on top of the boom?

7 The designs are maximised for gain.

8 What is the bandwidth of a NBS designed antenna?

9 Has anyone written a program specifically for an NBS antenna so you can calculate the element lengths without relying on tables and graphs?

10 Once designed the NBS design will probably work very close to parameters. But strictly speaking the antenna will only work very close to parameters if the antenna is 3 wavelenghts above ground. But for reception purposes on VHF, you can probably ignore effect of ground and no further design is probably necessary. (Lets face it with most bought antennas for receivimng, you just put them up. You don't start altering element spacings etc.)

From this, may one assume you envision having one
transmitter per building?

> would be limited to the building for all
> practical purposes.

This is practical for the AM broadcast band,
usually towards the low end around 550 kHz.
Search Google for "carrier current" radio
stations to get info on this technique.

Due to the relatively short wavelength of the
FM broadcast frequencies, a power line would
be too good an antenna and your signals would
be propagated beyond the confines of the
building. And they still might not reach where
you want them too. Still, it might work if
you could select the "right" power line to
excite.

The usual technique for limited-range VHF
(which is what FM broadcasting is) transmissions
is to install leaky transmission lines throughout
the desired coverage area. I have seen this
done to provide FM broadcast coverage inside
tunnels. In this scheme, a coaxial cable is
constructed with holes in its outer shield.
This couples a small amount of signal from
inside the cable to the outside surface of the
shield from where it is radiated into the
space immediately adjacent to the cable.

The obvious drawback of this scheme is the large
cable installation necessary for an extensive
coverage area.

> Another possible solution that I can't find
> an answer to would be to put the signal on
> an unused TV channel if the building is wired
> for cable.

Or combine a milliwatt-level FM transmitter output
into the other RF sources (TV channels) driving
the cable system. FM radios near the cable
outlets would pick up the signal from cable leakage.

> I've done a lot of Google searching but can't
> find anything specific.

Yeah, you need key words. Other than "carrier current",
or "leaky transmission lines", I can't come up
with any. I'll bet somebody else here can, though.

True frequency and waveform agility is the goal in SDR . Wideband, or controlled multiband, is needed. Ham requirements are well met at present with a variety of antenna designs that are nearly periodic in a fairly narrow frequency coverage, a fairly easy problem to solve.

There's an interesting analogy to this situation playing out in the airwaves right now. My understanding of this situation is as follows (and may be a bit incorrect).

Some years ago, the FCC decided to allow a company which I believe was called Fleet Telecommunications to set up some digital-packet-oriented communication on a set of frequencies in the 800 MHz range. These frequencies were located quite close to the 800 MHz narrow-band FM channels allocated to publics-safety ground (trunked police and fire systems, etc.).

There was concern expressed at the time that these digital channels might cause interference with the existing analog channels (intermodulation and receiver desensing, I think). The FCC agreed to allow the allocations, on the condition that the digital operator ensure that interference to existing allocations would not occur or would be abated.

Subsequently (I'm hazy on the details) Fleet either went out of business or was bought up... in either case, Nextel ended up as the owner of these 800 MHz digital allocations. Nextel has used them as the basis of much of its current-generation cellphone system.

The result: significant, and sometimes very severe, interference to public-safety radio operations. There have been numerous reports of police and firefighters being unable to use their radios successfully, when in proximity to Nextel cellular sites. This has resulted in very real danger to life-and-limb for police officers and firefighters.

Nextel has taken some steps to abate specific instances of this (reducing power) when it's called to their attention, but the problem remains.

There's a whole massive brouhaha taking place now, about "rebanding" the 800 MHz spectrum. This will probably involve consolidating the public-safety frequencies (requiring modification or replacement of much equipment - Nextel has offered to pay $billions to do this but there's concern that it'll cost twice that much), and moving at least some of Nextel's cellular allocations upwards to a higher frequency band. Nextel wants a big block of spectrum space in compensation, while other companies claim that the FCC has no legal authority to simply hand over that space to Nextel and that the law requires the spectrum to be auctioned to the highest bidder. No matter what the FCC decides to do, it's likely to end up being challenged in Federal court and delayed for years.

It's a horrible mess. Some claim that the FCC *could* have acted, on its own authority, to order Nextel to shut down operations in the interleaved bands, because their system is apparently violating the "we will not cause interference to other licensed operations" clauses which were part of the original Fleet allocation grant. The FCC has apparently asserted that it doesn't have authority to act on its own in the absence of a formal legal complaint from a public-safety radio organization... and no city or county or state has been willing to file such a complaint (perhaps because the cost of pursuing it against a deep-pockets company like Nextel would be very high indeed).

I agree that if BPL is rolled out en mass, it _is_ likely to cause serious interference with HF operations (amateur and otherwise), and that the momentum of "Hey, we've invested billions to field BPL, you can't just shut us down" is likely to override the original "No, there won't be interference" promised.

A few comments.

This "ground" wire, for all intents and purposes, is just a wire running around your house -- as far as this RF signal is concerned (I assume it is in the 2GHz 802.11 range) Whether you use this wire or run any old wire around the place, you have the same type of thing -> as far as your desired RF is concerned.
You must have a small capacitor in this line, however. I would think that anything between 1 pF and 50 pF is ok. This will greatly help with most problems in connecting up to the building power line ground system mentioned in ther posts.

NEVER to bounce back? Shortwave radio is that fragile? Must not be much keeping it going right now.

If there's more people who actually want BPL more than SW radio, then maybe they should have it. However, I seem to have less faith than you that BPL actually works. I do have faith that people won't spend money on a system which is unreliable.

Stopping BPL is simple. It's a political numbers game. Unfortunately, there's more potential customers for high speed internet access than there are SW hobbyists. I'm sure you've noticed that no Democrat is taking an anti-BPL stance. BPL has already been approved in a couple of areas.

Or, just maybe, the politicans expect BPL to fail or succeed on it's own merits. If it fails on it's own, then nobody gets the blame for keeping it away from the customers.

No, they *demand* a particular fixing method! (See 3.)

>7 The designs are maximised for gain.
>
As well as NBS could do it with the tools available to them at the time
(a hacksaw, mostly). Almost 40 years later - the work was actually done
in the mid-1960s - we have much better tools and wouldn't say those are
optimised designs any more.

>8 What is the bandwidth of a NBS designed antenna?
>
With or without losses due to the bandwidth of the matching circuit?
You'd have to model it; but the NBS designs are not noted for being
wideband.

>9 Has anyone written a program specifically for an NBS antenna so you can

In order: yes; yes; it depends how on the particular yagi, the
particular installation, and how much performance you're prepared to
sacrifice; certainly lots of people do; but that doesn't make it right.

I see, Frank. You are just a might-&-money makes right sort of guy. Maybe if
the FCC will just authorize all U.S. hams to run 10KW on MF and HF
frequencies, and give us full immunity to any interference claims, amateur
radio can co-exist with BPL.

That's real interesting about Nextel. My experience with the 800 MHz bands (LTR trunking systems) ended before digital cell phones existed, but I can certainly believe that frequency spreading must cause some com channel interference if you are near the transmitter site. Well, anyone who really believes that the FCC will mitigate interference to amateur radio that is caused by big-lobbying power companies should also believe in "temporary taxes" and Santa Clause.

FYI,

I have been in communication with Mr. Vincent. There are two pieces of info which I have acquired which I find intriguing:

1) Mr. Vincent states that testing is now occuring at a facility that is well known for viable, independent testing (not a ham facility) (I am familiar with the facility);

2) Mr. Vincent will be giving a talk at the August Boxboro NE Hamfest.

I applaude him for these two efforts and am looking forward to seeing his results.

The answer must be here but after some searching I can't find it.
There is all sorts of conversation about ground rods and dissimilar
metals but I can't find the basic answer I need -- How do you make the
steel to copper connection? Do you simply clamp galvanized steel to
copper? Thanks.

Hi Cecil,

Man, when I ask for you to humor me you certainly do it up brown!!

You've performed a magnificent job of detailing all the reflections and re-reflections in the 1/4 wl transformer replacing the tuner. That performance really took a lot of work, and I greatly appreciate it.

I haven't yet finished reviewing it to the point of verifying in my mind all the various voltages, but I appreciate that the numbers came out correct.

However, I have another request for you. Can you find any forward voltages that are appropriate to plug into Steve's Eq 9 and obtain 133.33 watts PFtotal ?

Walt

Cecil, I found the two Vfwd's we're looking for. They are derived from V1y and V2y. 70.7 v and 10.94 v. The interesting part is that 10.94 v is the exact increase in voltage resulting from adding 33.333 w to 100 w. This I knew many moons ago. But one would never find this Vfwd without performing the complete reflection analysis you performed. With this, plus the fact that a reflection analysis on a stub matching configuration would not reveal this forward voltage still makes Steve's Eq 9 invalid for general use. This is because the re-reflected forward voltage there, 40.82 v added to the source voltage 70.71 v does not equal the real total forward voltage of 81.65 v.

Therefore, my final comment on Eq 9 is that it works in specific cases but it certainly is not valid in general.

Thanks again, Cecil, for the elegant reflection analysis, bravo!

Walt

The FCC's likely to look to the complaining, and responding, parties
to present evidence and research and expert testimony about the issue,
I believe. The big communications companies can afford to throw large
amounts of money at their side of the issue, churning up large amounts
of paperwork, studies, and so forth. In order to hope to win the
case, the public-safety organization would have to try to refute these
studies and reports-from-experts with their own. I suspect it'd run
into a lot of money.

3724. Shorted 1/4 wave stub ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-09 19:59:25 UTC
From: Henry Kolesnik <kolesnik@sbcglobal.net>
Message-ID: <x_Jxc.5407$kT5.594@newssvr22.news.prodigy.com>
Source record: 93679

I know that a shorted 1/4 wave stub exhibits a very high impedance. But for the 2nd harmonic it's a 1/2 wave stub and exhibits a very low impedance or a short. There are claims that this can be used to filter the even harmonics. Shorts can't diisipate power and must reflect, so how does a stub work?

>
> I see, Frank. You are just a might-&-money makes right sort of guy.

Well, as scurrilous libel goes, that's a step up from toxic waste dumper, but you've missed the mark again. I was making a democracy arguement. The voters who want high speed access vastly outnumber the voters who are radio hobbyists. If BPL can actually deliver on it's big promises, radio hobbyists will have slim clout in Washington. Being a radio hobbyist isn't a God given right, or a natural right, or even a constitutional right.

But I think there's more to the democratic free choice arguement. What if BPL is really a goofy idea which won't work? What's the gain for any politician to block a popular, yet doomed approach? His opponent will grab the the glittering promises that the BPL folk are making, and use those promises to take votes from the "anti-BPL choice" candidate. Don't think the voters really know the difference.

I see two possible scenerios:

1) BPL works as promised. It delivers high speed internet access to millions of users at a competitive price. Since cable, DSL, microwave and sattelite providers also have to compete with the BPL providers, every user of high speed access benefits from BPL. Thousands of radio hobbyists lose. Neither the Democrats nor Republicans choose the thousands of hobbyists over the millions of internet users.

2) BPL flops. It can't provide adequate bandwidth for more than a small number of users. The small number of users can't make up the costs of the system and BPL goes the way of the personal jet pack. Politicians who might

have opposed "system choice" before it proved itself unworkable come out smelling like a rose.

>Maybe if
> the FCC will just authorize all U.S. hams to run 10KW on MF and HF
> frequencies, and give us full immunity to any interference claims, amateur
> radio can co-exist with BPL.
>
> ak
>
>

Hmmm. Do you think radio amateurs have enough friends in Washington to get anything like that? Or maybe, if amateur radio interferes with a BPL system which benefits millions, the FCC will restrict amateur radio to protect BPL?

But, if you're convinced BPL is workable and won't flop, let me suggest you join the dark side and invest in BPL. Dump your entire networth into BPL. Borrow more and toss that in too! Rewards go to those the bold who see the truth, while timid fellows such as myself stand on the sidelines. Thanks to your clear foresight, you'll soon be able to buy all the accouterments of capitalism. Buy a diamond handle cane. Buy that Top Hat you've always wanted. Buy a hand-made Isotta-Fraschini touring car with leopard skin upholstery and gold plated hardware. Don't forget to buy a chauffeur!! You'll forget about SW in no time!

http://www.prospectstreet.com/portfolio_listing.htm

Oh wait. Manassas dumped Prospect Street. Seems like they could only get 200 workable BPL connections in 6 months.

Nevermind.

Put a Tee on a coax line and connect the stub there. At the H2 there is
a short and reflectinonback up-stream.
Common filters you see everywhere are "reflective" by nature / design as
well. They have other than Zo off frequency and therefore reflect the
unwanted stuff back to the source. It has to be able to handle it.

Help any?

Hi Hank, A 1/2 wave shorted stub looks like a series resonant circuit. It
makes a good notch filter, which is one of the Amateur applications that I have
used. You are right, they don't dissipate any power since Power=I**2*R and R
equals zero.

============================

R is not zero. It can be several ohms. And lots of amps can flow.

Just to add a 1/2-wave shorted stub also makes a mess of the tuning of the remainder of the antenna system at all other frequencies. It must be designed "in".

Just get a good clamp out of steel or copper and really torque it so you get good contact. Good contact means there's metal-to-metal with no space for air or water. Not all strands will get this molecular contact but most touching will. Make sure the clamp is a cheap pot metal one as it'll corrode and fall off if it doesn't break while your torquing it. If you hve any Thermit, it'll make a better joint.

That should be fairly obvious to the most casual observer. :-).
In the receive applications that I have used a 1/2 wave shorted stub as a
notch filter, I can assure you I did not have lots of Amps flowing.

In this particular case, the G5RV might be a better choice. In many other instances other antennas will far out perform the G5RV and be easier to match across all bands without being picky on some bands like the G5RV is. You'll have fun in either case.

>>Where is says:
"With my technique, I reduce the inductive loading that is normally required to resonate the antenna by as much as 75 percent . . . by utilizing the distributed capacitance around the antenna," he explained.

"I looked at all the different approaches used to make antennas smaller, and there seemed to be good and bad aspects" to each, Vincent said. "A helix antenna is normally known to be a core radiator, because the current profile drops off rapidly; they are just an inductor, and inductance does not like to see changes in current, so it's going to buck that.

"What I found was that for any smaller antenna, if you place a load coil in the middle you can normalize and make the current through the helix unity; that is, you can maximize it and linearize it," he added. <<

Let me guess, he "snaked" the part of the radiator in the plane, rather than winding it as a coil, then added loading coil and and perhaps capacitive/inductive top hat (like Force 12 uses and old Ukrainian patent)

Cecil, have you noticed the statement about the loading coil current? Buck that!

Video on demand??? They gotta be outta their pea-pickin' minds.. Where they gonna get the sort of bandwidth they need to provide all those services? It's not like they're going to have ADSL type bandwidths available to every home (and the more homes they connect, the less bandwidth they will have available for each).. and I have problems at times with Video on Demand with my ADSL line (supposedly 10 Mbit, but I rarely acheive download speeds greater than about 400Kbit).

> like a great idea. I hadn't thought of that.

It's easier to do it in steps.

Step 1.
100W XMTR---50 ohm line---x---1/4WL 86.6 ohm line---150 ohm load

Calculate all the forward and reflected components.

Step 2.
100W XMTR---50 ohm line---x---1/4WL 86.6 ohm line---y---1WL 50 ohm line---150 ohm load

All other forward and reflected components remain the same.
Calculate the forward and reflected components on the 50 ohm line
going to the load.

Dave:

An exposed copper to galvanized steel connection will quickly lose the zinc, and the steel will rust profusely. So, whatever approach you use, put lots of weatherproofing over the joint. Personally, I use thin stainless steel between the two dissimilar metals along with Penetrox and then weatherproof with roofing tar. The professionals use a special crimp connector or a purpose designed CadWeld connection.

Walter Maxwell wrote:
> However, I have another request for you. Can you find any forward voltages that
> are appropriate to plug into Steve's Eq 9 and obtain 133.33 watts PFtotal ?

Here is a quote from an earlier posting:

Continuing and calculating interference energy at point 'y':

V1y = VF2(1-rho) = 96.58(0.732) = 70.7V (100W)

V2y will be VR3(rho) = 40.82(0.268) = 10.94V (2.39W)

VF3 = 70.7V + 10.94V = 81.65V. (133.33W)

--- So ---

PFtotal = |VFtotal|^2/Z0 = 81.65V^2/50ohms = 133.33W

PFtotal = |V1+V2|^2/Z0 = (70.7V+10.94V)^2/Z0 = 133.33W

How's that?

Hi,
I may be acquiring a tower and beam from an SK. I am having problems trying to figure out what kind of beam it is. I think its been up there awhile. It is a 4 element beam with two driven elements spaced about 1 to 2' apart. Its probably a 10-15-20 beam. Any help would be appreciated.

1) DSL in any form on the market today is not capable of 10Mbps. 7.1 is it at present, and rare. Most DSL in my area is sold as 256/256, the next step, which just changed here (old was 620/256) in Qwest country, is 1500/768. Most non-business DSL circuits don't go beyond this.

2) If you are not getting the BW your ISP and local loop provider show in your Terms of Service agreements, and they have not attempted to remedy the problem (assuming you complained), you have grounds to complain to your local PUC. As well as the Better Business Bureau, etc.

This is a decent DSL info link -

> increase in voltage resulting from adding 33.333 w to 100 w.

Yes, that's superposition of voltages in action. All it takes to exist is
some constructive interference energy without which, superposition would
not occur. Without the constructive interference, the two waves are not
coherent and add like two incoherent waves.

> This is because the
> re-reflected forward voltage there, 40.82 v added to the source voltage 70.71 v
> does not equal the real total forward voltage of 81.65 v.

Let me say it again. Your re-reflected voltage and Steve's re-reflected
voltage are not the same quantities because they have completely
different definitions.

Think about that. Why would you expect your re-reflected voltage and Steve's
re-reflected voltage to be the same value when they have completely different
definitions?

> Therefore, my final comment on Eq 9 is that it works in specific cases but it
> certainly is not valid in general.

It is valid for Steve's definition of re-reflected voltage. It is not valid
for your definition of re-reflected voltage. You guys are NOT using the
same analysis model. I don't know how to say it any clearer than that.
Steve's analysis model works for him. Your completely different analysis
model works for you. You both get the same answers but you are using
different models to get there.

Jim Kelley, as a physicist, defines energy transfer different than I, as
an engineer, do. Therefore, his values of energy transferred and mine will
NEVER agree. You and Dr. Best are in the same position. Your re-reflected
voltages and powers will NEVER agree because you define them differently.
If you accept his definitions, you will get the same results that he does.
If he accepts your definitions, he will get the same results that you do.
But neither one of you is willing to budge an inch.

Fill the gas tank and wine cooler and take an HF mobile rig into a BPL "test area" and tune around like I did and come to your own conclusions Cecil. My direct experience with the stuff clearly indicates the utter destruction of HF radio within large radii anywhere it's deployed.

Luv the "we need to cooperate . . yadda, yadda, with the power utilities . . yadda, yadda . ." sugestions. Yeah right: I've also "interfaced" with a power utility or two in my time on the general topic of "Broadband RF interference: . . Might as well have tried to cut "mitigation" deals with Al Queda.

The good news however is that it's basically an artifact technolgy, it's time will never come. In the meanwhile we have to keep leaning on the sumbitches so keep shipping monies into the ARRL Spectrum Defense Fund.

> stub work?

Consider the following configuration:

```
Source----ideal 1 WL feedline-----------+-----matched load
|
|Stub
|
|
open
```

If the stub is 1/4WL, the forward voltage and reflected voltage in the
stub is the same as on the feedline. At the mouth of the stub, they
are 180 degrees out of phase and superpose to zero volts which obeys
Ohm's law and delivers zero power to the load.

Double the frequency. That makes the stub 1/2WL. The forward voltage and
reflected voltage are essentially the same as in the 1/4WL stub but this
time they are in phase and superpose to a maximum value which obeys Ohm's
law and delivers maximum power to the load.

Absolutely nothing except superposition and interference happens at the
mouth of a stub. All the reflected action happens at the physical open
circuit. Virtual impedances are only a V/I ratio and CANNOT cause
reflections. Absolutely no reflections are happening at the mouth of
the stub (unless a physical impedance discontinuity exists there).

Consider this. If a stub really presented an infinite impedance, you could
simply remove it and nothing would change. Something inside the stub happens
to cause that infinite virtual impedance. Hint: Stubs have a near-infinite SWR.
To understand that assertion, consider how much voltage exists at a voltage
minimum inside a stub. It is nearly zero.

> equals zero.

Stubs dissipate the maximum amount of power possible since the SWR on a
stub is nearly infinite. If you don't believe it, hang a Bird Wattmeter
halfway down a stub. The ratio of Vmax/Vmin and Imax/Imin is very high.
If the stub were lossless, the SWR inside a stub would be infinite.
After all, a stub is merely a shorted or open piece of transmission line.

>model works for you. You both get the same answers but you are using
>different models to get there.

Cecil, I don't recall defining re-reflection, nor do I recall seeing any definition of it by Steve. A re-reflection is a re-reflection. It's simply a reflection of a wave established when an EM wave encounters a discontinuity in its otherwise smooth path. How else can it be defined?

A forward traveling EM wave that is a result of re-reflection has no different characteristics than any other EM wave, and therefore cannot be distinguished from any othe EM wave.

Now let's take another look at Steve's Eqs 7 and 8. There is no question here that there is anything different from being general. In fact, they're straightforward, valid, and viable. They are general, and are understood in exactly the same manner by any engineer speaking transmssion line language.

Now let's look at Eq 9. It too, is straigtforward, and it is entirely general if the user knows that V1 and V2 are each delivered by two different sources of energy. However, in general, V1 and V2 cannot be added, or superposed if the energy involved comes from only one source. Note the operative word is 'in general'. If there is a specific case, as in the 1/4 wl transformer where there are two reflections that are re-reflected into the forward direction, the Eq works, but it doesn't work in the configuration that was replaced by the 1/4 wl transformer. Consequently, Eq 9 must be invalid in general.

I simply can't accept that there can be more than one definition of re-reflection. Furthermore, anyone reading Steve's paper and encounters Eq 9 believing it valid in general, and applies it to a general case, he has no

assurance he's going to get the correct answer. The chances are he won't, the same as I and others did. If Eq 9 is Steve's piece of cake he can't have it and eat it too.

And as I said in a much earlier postI must remind you that Steve made a vital error when he said:

"When two forward-traveling waves add, general superposition theory and Kirchhoff's voltage law require that the vector sum of the individual forward-traveling voltages such that VFtotal = V1 + V2."

This statement is not true in general. This statement would be true in general if you replace 'forward-traveling waves' with 'voltage', and specified that the statement is following simple circuit theory. This is because only in special cases will it be true where the voltages are forward-traveling waves. You know very well there are cases involving transmission lines where circuit theory fails and transmission-line theory must be involved to obtain the correct solution to a problem.

This is what makes Eq 9 clearly invalid in general.

Well I remember doing the same thing using a Mercedes car antenna
which had a nice drive on it where the plastic cord was changed to
wire. Worked O.K. when running the wire thru telescopic fishing poles.
The first printing of this sort of design was one described in
in many electrical journals in early 1970 . The antenna was sold by
Racal
(type AE3062) which was an all frequency monopole.
They used a glass fibre column and at the base were two driven spools
one of which had a flat silver coated copper tape and the other had a
flat insulator tape. These tapes were both joined to form one complete
tape which was driven up the mast (fibre glass tube column). In one
version they had a frequency discriminating bridge sensor for an
automatically tuned servo-system.They had two forms of antennas for
commercial and military aplications, 2-30 Mhz and 4- 30 mHZ with poles
65 foot high and 125 foot high. Unfortunately it does require a ground
plane to cover all frequencies a problem I over came with my
particular antenna by using a full dipole structure.
Like you I cannot see how a moveable conducting tape inside a fibre
glass tube
can be seen as a new invention or antenna device when the above
description
was so widely printed in the U.S. and sold commercially to boot!

Steve defines re-reflected voltage as voltage reflected from the load
multiplied by the rearward-looking physical reflection coefficient,
(Z1-Z2)/(Z1+Z2). That's certainly not the definition of your reflection
coefficient for reflected voltage. Why are you surprised that you two
guys get different values of re-reflected voltage when you are using
entirely different voltage reflection coefficients?

> Cecil, I don't recall defining re-reflection, nor do I recall seeing any
> definition of it by Steve.

And that, in a nutshell, is the entire problem. You implied your definition
of re-reflection in _Reflections_. Steve implied his definition of re-reflection
in his QEX article. They are NOT the same definitions. Your definition of re-
reflected voltage involves a reflection coefficient of 1.0 at your virtual short.
Steve's reflection coefficient is the *physical reflection coefficient*, not the
virtual reflection coefficient and is NEVER equal to 1.0.

> However, in general, V1 and V2 cannot be added, or superposed if the
> energy involved comes from only one source.

True for your model - not true for Steve's model. You guys are NOT
using the same model. You are as far apart as the wave/particle
controversy.

> I simply can't accept that there can be more than one definition of
> re-reflection.

But there is, Walt. The S-parameter analysis defines re-reflection differently
than you do. In the equation, b2 = s21(a1) + s22(a2), the s22(a2) term is
the re-reflected voltage. It is defined as the voltage reflected from the
load multiplied by the physical reflection coefficient looking into port 2
when the source is replaced by Z0. That is NOT the way you define re-reflected
voltage.

That statement is true in general for an S-parameter analysis. You and
Dr. Best are not using the same analysis model.

> This is what makes Eq 9 clearly invalid in general.

Eq 9 is valid for an S-parameter analysis. I doubt that you are going
to be able to discredit the entire field of S-parameter analysis so
you might as well accept the fact that you are calling a shrub a "tree"
and Steve is calling a shrub a "plant". Either both of your are right
or both or you are wrong.

Unless you want the connection to last for 20 years, use a simple clamp.

As for me, like many others, I've never kept an antenna for longer than 6 months.

Further:

Reason why I looked at technical note 688 was because I thought I could avoid using models in antenna computer programs. As far as I can see in 4nec2 and Eznec you *cannot* input boom data. So, I thought following note 688 I can more easily design an antenna because it includes a table so you can take account of the boom. The test people obviously constructed the yagi designed for maximum gain and used a boom to figure out the boom corrections. This is dandy or looks good when somone like me does not want to spend ages designing.

The way it reads is that if you follow note 688 you can easily design your own antenna.

But, as always I get stuck with DE. Whether looking at note 688 or when I'm messing with 4nec2.

I see now that in the original test yagi, DE was a 1/2 wavelength folded dipole with the test element diameter of 1/4" matched to 50 Ohms with a double stubb tuner. There is not enough information as to the construction of the folded dipole to be able to replicate one to use as DE. Who knows if 468/f was used to get length for DE, who knows what the spacing between the elements of the folded dipole were.

Yet, I think whoever wrote note 688 expects a "designer" to put almost whatever he wants for DE, and is expected to keep the calculated dimensions regarding the parasitic elements.Obviously that is how note 688 reads. The problem is this though isn't it, it's okay if DE is in the clear of any parasitic elements, because then there is no influence on DE and you can l look in textbooks to calculate what the dimentions should be etc etc. DE would be a simple dipole on it's own in free space or whatever. But of course in a yagi DE is immersed in the fields created by the parasitic elements which influence a lot of things to do with DE. So how on earth can you design DE and establish Z etc without some sophisticated mathematics that take into account the effect of the parasitic elements on DE. Could you (whoever is reading this) know what to do with DE?. Could you calculate Z and dimensions for DE just looking at the information given in note 688?

(I think it's possibly implied that whatever DE is, it ought to be a folded dipole - maybe. Not a simple hertz dipole for instance.)

Anyway reasons why looking at note 688 is a ruse: I'm wanting a wideband antenna and I'n not sure if a design for 159 Mhz will have a bandwidth of 6 Mhz. I wanted NOT to use a folded dipole so an NBS design is no good. And can you actually make a design relying on the procedure in note 688 anyway. Possibly though a basis of a model in an antenna program.

All this is part of my learning curve BTW.

I'm not really sure about that. Maybe this is not expected, rather perhaps
there is an implication DE ought to be a folded dipole.

Whenever anyone produces a design for a yagi, who has built a practical
model, whether a test model like NBS did, or whether a model built by Joe
Ham, then the DE is already designed. Most people who want to build a yagi
don't want to design from scratch, they just want to be presented with a
design methodology that's simple, that allows for some slight variation in
materials or method of fixing.

So the design methodologies that appeal are:

Copying exactly someone else's design.(No design involved)

Trying to design with Technical Note 688. (Looked promising at first).

Taking someone's design and adjusting for variation in element diameter and
boom size using some program or other. (This involves ELE.EXE I think).

Taking a model and designing with that with a program. But I've got the
impression, rightly or wrongly, that going this route is getting away from

the concept of "simple design methodology". I think that stems from my inability to have noted these programs allowing boom parameters to be inputed, and I'm totally in the dark about DE in these programs.

All the really simple methodologies have as starting point a practical proven design. All one is doing is making certain kinds of alterations: frequency, boom size, element diameters, and if you really want to adventurous, alter element fixing method, but that could be an alteration too far. That's the only things I'm interested in messing with. And I'm looking for the design methodologies that allow me to make these kinds of alterations. I'm not really wanting to be in the business of designing DE or spending hours experimenting.

I've yet to determine whether I can classsify using models in an antenna program as being a "simple design methodolgy" given the kinds of alterations I might want to make.

This is a key to understanding for me.

>

To linearize the current you need to place capacitance at the top.

His design-as stated in the press release --calls for about 0.4 waves electrical length as a helix (0.008 inches x 100 turns @ 1 Ghz). This is electrically long for a 1/4 monopole configuration. So the design is electrically long but very physically short: Stated 15 inches high for 15 meters. (This means that if you don't slow the wave, there is more than one current max.) This will drive the feedpoint impedance up and improve bandwidth. It also increases ohmic loss. Thus the tradeoff.

A loading coil on the helix will help linearize it--I'm there so far. Distributing the capacitance is trickier.

In fairness, we don't know the design, but there is nothing new that appears to me--in my opinion--in these stated approache(s).

The press releases claim high efficiency and broad bandwidth.Of course, these are relative terms. 1/15 wave high monopoles with excess of 10% BW with gains of -1.5 dBd are prior art. If you make a bit taller then it becomes much more interesting.

BUT we don't live in a single band world anymore. In fact, we don't live very much in a monopole world anymore: the trend is ground independent, wideband antennas, or at least multiband ones..

There's a lot more to antenna issues: anyone who thinks the issue with RFID antennas is gain and size doesn't understand the issues with RFID, for example. Right, Wayne:-)?

Losses are a huge concern in very compact designs--placing them on substrates loads them intractably, for example.

Also, knowledge of the prior art is essential for making a claim of 'revolutionary' antenna technology. I have not seen anything in the press releases that --in my opinion--indicates a good knowledge of the prior art by the inventor. He may have it, but it is not apparent from these statements. He obviously has a good working knowledge of the problem. That's not the same thing.

Anyway, fun stuff. The bottom line on what appears--to me-- as the claim relevant to hams: If you need a -1 to -2 dBd short monopole that covers the CW portion of 40M, for example, this may be useful, in my opinion. If you want to stick it on your roof then be prepared to have a big roof:-).

The point being of course that if someone gives me a model, what do I know about the practical construction associated with that model. Does the model file (NEC or EX file) include data about element fixing method for instance. Probably not. So unless I can input these practical parameters into the program, and these paramters serve to make alterations to the elements, diameter and spacings, how can I arrive at a practical design having followed a "simple design methodolgy".

This is why Technical Note 688 looked so promising at first. The design methodology is simple and you can input details or alterations concerning the boom size and element diameters and end up with a practical design in no time at all. There are apparant problems with Note 688, as you say with Table 10 being possibly practically useless without there being a detailed specification of element fixing.

Source record: 93622

Hi. I'm wanting to "design" using a "simple design methodolgy". As far as I can tell that means avoiding using models and antenna programs because I think designing a practical yagi from a model is *not* a simple design methodology. That's my impression.

So I think the best option I have is to take a practical design and use the principle of scaling, and using a program that will make adjustments to the element lengths for an alteration in element diameters and a program that will make adjustments in element lengths for alteration in boom size. I'm pretty sure element spacings will need not to be altered given some reasonable alteration in either element diamters or boom size.

(Do these correction programs assume a particular element fixing method I wonder!!. Where are these programs. I only know of ELE.EXE)

I'm looking for a practical design that uses a hertz dipole as DE, not a folded dipole. And it ought to be wideband well, a bandwidth of about 4% of the center frequency.

Boom needs to be metal.

I'm looking to make the center frequency 159 Mhz. So any practical design I suppose is likely to be a VHF yagi not too far removed from 159 Mhz.

There can be a balun arrangement or not, but I don't want to feed a balanced DE with unbalanced coax.

My antenna is to be a receiving antenna.

My email is:

hobby_electronics@REMOVEntlworld.com

Please remove REMOVE.

Thanks.

OK -- I'll go through it.

If BPL works as promised, it will benefit millions. The BPL folk promise high speed internet access at under $30.00 a month. Every other high speed access provider will have to compete with that price. More than that, BPL promises continual power line monitoring and millions of dollars for local governments. That's what BPL promises. If BPL can come through on these promises, BPL will benefit millions.

Can BPL come through on their promises? I sure don't think so. Most people with a technical background don't think so. There's a hundred reasons to think that BPL won't be able to fulfill it's promises.

But how can it be PROVEN that BPL will fail? By talk? By computer simulations? I'm sure my opinion doesn't cut it. The ONLY way to prove that BPL cannot fulfill it's glittering promises is to -- let it fail.

BPL is being allowed. That hardly means that BPL will wipe out the SW bands. Approval was the easy part. All it took was promises.

But now, it's put up or shut time for BPL. So far, BPL's reality check doesn't seem to be going very well.

Please name the politician who would stand in the way of the BPL promises. If they did block the BPL promises, then they would hear from the thickheaded knee-jerks would be ABSOLUTELY CERTAIN that the FCC was in the pockets of the fat cats who want to keep access prices high.

I hope I've made my point clearly.

Of course not for receive. Here's the statement to which I was objecting:

"... they don't dissipate any power since Power=I**2*R and R equals zero."

R is not zero half-way into a shorted 1/2WL stub. For a lossless stub, R
is infinite at the half-way point. Stubs have considerable I^2*R losses
during transmit. Of course, if you are using them to notch filter out
unwanted receive signals, you want them to be lossy.

> How would you measure the current in the stub during transmit using equipment
> the average ham (like me) has laying around the shack ?

Wrap ten turns of pickup wire on a ferrite toroid. Use a dummy load
to calibrate it by running the dummy load wire through it. Then install
the shorted stub wire through the ferrite toroid and make the measurement.
Roy Lewallen describes how to measure RF current in his article in "The
ARRL Antenna Compendium", vol 1, in "Baluns: What They Do and How They
Do It."

Or install a one ohm resistor at the stub short and measure the voltage.
An oscilloscope will do. You don't need super high accuracy.

For the following stub, we can estimate the value of the current at
the short in the stub assuming a lossless line. The source is a 100W
Signal Generator equipped with a perfect Circulator and Load

```
100W SGCL----50 ohm feedline-----------+---50 ohm load
|
|1/2WL Stub
|50 ohms
|
short
```

No current reaches the load. The forward current is 1.414 amps and the
reflected current is 1.414 amps on the feedline and inside the stub.
100 watts of reflected power is being dissipated in the circulator load
resistor. The RMS current at the short is 2.828 amps, the in-phase sum
of the forward and reflected currents. The peak-to-peak current at the

short is 8 amps.

The only reflection point in the entire above system is at the short
at the end of the stub. No reflections occur at '+'.

3770. Simple practical designing with antenna modeling programs

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-10 12:38:08 UTC
From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <2ir30fFpnd30U1@uni-berlin.de>
Source record: 93625

Are these points true?

The following is the simplest way of obtaining a practical yagi design using an antenna modeling program:

1 If you use a non conducting boom then you can build a practical model using the element lengths in the model.

2 For a VHF yagi in the clear you can assume freespace.

3 A simple straight wire in your model that is made source is DE and is treated as a simple hertz dipole by the program. So the values given for R and J are the values you would measure having a hertz dipole as DE. This is true for the model and would be fairly accurate if the boom was non conducting and reasonably in the clear in the practical design.

4 It is easy to scale for frequency in antenna programs.

5 It is fairly easy to alter element diameters in antenna programs and to obtain a redesign that maintains the original performance characteristics.*

It seems to me that if one is prepared to use a non conducting boom, a hertz dipole as DE, then the model is pretty much the practical design.

Not sure about impact of a balun or the feedline.

---
*
http://www.cebik.com/32m.html

The second kind of answer involves adapting a given antenna design to a new diameter material. Suppose that a designers specifies 0.1875" (3/16" or 4.76 mm) elements. The builder has a stock of either 0.125" (1/8" or 3.18 mm) rods or 0.25" (1/4" or 6.35 mm) rods. Will he or she need to adjust the element lengths of spacings?

The answer is "yes." In fact, without making such adjustments, the antenna will not perform as originally designed. There are two major reasons for this result. In general and first, both driver and parasitic elements lengths require adjustment with every change of diameter. The general goal is to arrive at elements whose self-resonant frequencies are the same as in the original array. Second, the inter-element coupling changes for a given spacing of two elements if we change the element diameter. Element spacing does not change as rapidly as the element length for a given level of coupling when we change element diameter. However, it changes enough so that we cannot ignore the effects.

One of the simplest ways to accommodate a revised element diameter is to resort to a Yagi optimizing program. We simply plug into the program the existing design and specify the new element diameter. The program then churns out the revised design.

More antenna builders have general antenna modeling programs than have optimizing programs. There is a procedure that we can use to reoptimize a design for a new element diameter, although it has a pitfall from which we must guard ourselves. Here is how the procedure works.

1. Create a model of the original design and establish its operational characteristics.

2. Revise the model to use the new element diameter.

3. Find the frequency at which the new model shows the same operating characteristics as the original model did at its initial design frequency. If we are moving to a larger-diameter element, the new frequency will be lower than the old one. If we are moving to a smaller-diameter element, the new frequency will be higher than the old one.

4. Frequency scale the revised antenna model from the new design center to the original design center. Retain the new element diameter: the amount of performance change occasioned by the small frequency movement will usually not require a reiteration of this step. However, when enlarging or shrinking elements by more than a factor of 2, it may pay to make the change in two steps of scaling and checking.

At this stage, check the performance of the antenna across the passband used by the original design. In many instances, the model will suggest that we need not make any further changes. However, in some cases, we may need to adjust some element lengths to center the gain, front-to-back, and SWR curves as closely as possible to their original form (assuming that the original curves are the most desirable ones for our application). The driver length will have the greatest effect upon the SWR curve. Juggling the reflector length and the most forward director lengths can smooth out the performance across the passband, although rechecking the SWR curve may be necessary. For a given band-edge adjustment, alter the element that moves gain and/or front-to-back performance values in the desired direction with least adverse affect on the SWR curve. Finally, when reducing element diameters, you may need to increase the reflector spacing from the driver to raise the general impedance level back to that of the larger elements with which you began.

The pitfall in this procedure involves stopping at this point. Although the initial detection of the revised design center frequency and scaling that back to the original center produced element lengths that are very close to optimum, the element spacing moved in the wrong direction. The thin-element model increased element spacing, while the fat element model decreased the spacing. However, as element diameter increases, element spacing must increase to maintain the same level of coupling. Because we have adjusted element lengths, the spacing adjustments may not be dramatic, but they will be noticeable. Therefore, we need one more step.

5. If increasing element diameter, increase the spacing among elements by about twice the amount that the initial scaling decreased them. If decreasing the element diameter, do the opposite. Do not use a simple additive method, but instead find a multiplier based on the scaling ratio used in step 4. Take into account any revised positioning of the reflector in step 4. As well, check the driver, reflector, and most forward director lengths to re-establish the performance curves for the array.

Yeah, that gets to the heart of an important issue. Will BPL somehow be
profitable?

The quality of the reporting on BPL is, more often than not, poor:

http://moneycentral.msn.com/content/P81685.asp

That guy doesn't seem to have a clue about the technical problems that the
BPL system has to overcome. I suppose he figures that since the FCC doesn't
seem much worried about cranky old hams, then BPL is on easy street. I'd
think the financial press would have wised up after the dotcom blowout.

I did see a technically literate investment write up on BPL last year. That
guy thought BPL was a loser.

The ARRL is doing a great job making themselves available to reporters. The
better stories devote a significant part to the ARRL point of view. Still,
the stories often come down to BPL vs ARRL.

Here's a pretty good antiBPL site:

http://gobpl.com/

An interesting page from that site:

http://gobpl.com/sharkbites.html

Nor does he have a clue about how people choose to spend their money. For example he mentions that there is good market potential since 80% of the internet users are still on dial up. He seems to think that they will switch to BPL. But let's look at why they are on dial up. It is cost. Dial up is still the cheapest access and it will be cheaper than the projected cost for BPL. Unless they can get much closer to dial up in price, most will NOT switch. There's a dial up service around here that is only about $10 per month. Even the most expensive dial up in this area tops out at $20 per month. BPL won't be able to snag a major share of the dial users no matter what anyone would like to believe assuming their projected costs are accurate.

I would have to agree Cecil. The point is proven by the fairly shallow notch
afforded by a single stub (approx -20dB at VHF). I can do better with a
quality L-C combination.

Cecil, the only difference that can obtain between reflection coefficents is in
magnitude and phase. It matters not whether a reflection is established by a
physical discontinuity or wave interference, the result is identical.
>
>> Cecil, I don't recall defining re-reflection, nor do I recall seeing any

>Steve's reflection coefficient is the *physical reflection coefficient*, not the
>virtual reflection coefficient and is NEVER equal to 1.0.

Now I see your problem, Cecil, and that is because you still don't understand
why a reflect ion coefficient of 1.0 IS established when two waves equal in
magnitude but of equal and opposite phase occur at the match point. If the two
waves are of unequal magnitude the coefficient is simply less than 1.0. So I
repeat for emphasis, it matters not whether the reflection is established by
physical or virtual means. This is another error in Steve's article. He disputes
this established fact, saying incorrectly that a physical short is required to
establish reflections--totally wrong.

>> However, in general, V1 and V2 cannot be added, or superposed if the

>voltage.

Cecil, to perform an S-parameter test on an antenna tuner one would first
adjust it to match the input impedance of the line connecting it to the antenna
then disconnect it from the line and replace the line with a pure resistance =
to Zo. Now the input impedance is measured. Then the setup is reversed, placing
the Zo termination at the input and measuring the impedance looking rearward
into the output. These measurements yield the transfer impedance of the tuner,
but they don't yield the input and output impedances established during
operation. The reflections are not defined differently in either case.

>> And as I said in a much earlier post I must remind you that Steve made a vital

>you might as well accept the fact that you are calling a shrub a "tree"
>and Steve is calling a shrub a "plant". Either both of your are right
>or both or you are wrong.

Cecil, we don't need to argue the conditions concerning S-parameter analysis,
because I've put my finger on the problem you're having with this entire
discussion, that is you're (and Steve's) unwillingness to understand that wave
interference can establish a reflection coefficient of 1.0 without any physical
means.

This vital error in Steve's belief that physical means is required to establish
reflections is why he wrote his article for the express purpose of trying to

prove my writings in Reflection incorrect. The material in his article hasn't proven them wrong because they aren't wrong, he has merely shown the world that he doesn't understand the wave mechanics involved in impedance matching.

> thanks Dave Browne

In your situation I think you would be better off with the g5rv. With a good tuner you should be able to run on all the HF bands.

I have found, in the past, that a inverted L doesn't work very well without ground radials. I experimented with one that was fed at ground level, traveled up for 25 feet, headed east to a tree branch, and then south to another tree branch. Total length was about 96 feet. I first tried to run with only a ground rod but couldn't get a stable match. Then I started to add ground radials. They were just random lengths of wire, around 25 feet long, buried about 1 or 2 inched in the ground. As I added radials the matching became more stable and at around 5 radials everything matched up great and the antenna worked great.

I live in the desert so my ground conditions are different than yours, but you still may need the radials.

3776. Non conducting booms

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-10 14:01:37 UTC
From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <2ir7t9FprravU1@uni-berlin.de>
Source record: 93630

Anyone have experience of making VHF antennas with non conducting booms?

I think I ought to be able to employ a non conducting boom for a yagi design that is no more than about 50" (1.27 meters) in length. Must have sufficient rigidity.

I was thinking about using a square boom made out of some synthetic material (NOT wood). Obviously tthe material must not degrade over time in an outdoor environment.

Thanks if you can suggest a product.

Hi Dave

For searching the web, use Cathodic Protection as your search key.

As far as steel to copper, nickel is a good go between between the two metals. You can weld to steel with nickel and put a nickel coating on the binding area of the steel rod.

Richard, I thought you wanted a marine-band antenna? The center should be at
156.300 to 156.800 mHz and will cover above that fine, but not well below
it.

Hi Richard

If you can get some Cypress lumber to make your boom, it will last longer than you do!

We had 12 acres under glass, all of the greenhouses were made from Cypress rails which held the glass in place. They were 71 years old when we sold the place to a shopping mall developer.

These rails were only 2x2s with two dado's cut out for the glass and a decorative slot cut down each of the inside portions. They held the weight of glass just fine for all those years.

I'm following two threads with my antenna muses, I don't know which one is
going to come out on top:

engaging in applying scaling, and tackling what is required when changes are
made in element diameter and boom size of a tried and tested *practical
design* one that employs a metal boom,

or following the track that seems to involve simply scaling with a *model*
and the making of other adjustments to the model, (arising from element
diameter changes) where in practical terms the model is sufficiently
equivalent to a "practical design" by virtue of the employment of a non
conducting boom in the construction of the yagi.

But to your point:

Marine band is from 156-162 Mhz. Center 159 Mhz.

I doubt I would use a folded DE myself. More work...:(Normally, I
would just use a grounded DE, but in your case, you need to consider
how you would tune the antenna. IE: gamma match, etc...If you have no
radio that transmits, or an antenna analyser, it might be tricky..In
that case, probably the simpliest method would be to use a split,
carefully cut dipole DE, and hope for the best. The dimensions,
spacings, etc, are critical yes, but I don't think as critical as you
think. IE: I don't really worry too much about element mounting
methods, etc, when I build a yagi. Almost anything you slap together
should work pretty well as long as you measured carefully. When I once
made one for that purpose, I didn't have a transmitter. And I did use
a gamma match. I had no decent way to tune it up. So I just
guesstimated, and tuned the match for max signal, noise, etc..I don't
know how well it came out as far as the match, but the antenna worked
great.
A simple fast way to design an NBS yagi for any freq, is to use the
eznec demo. It has a NBS yagi as a demo, and it can be easily scaled
for any freq. MK

Okay, but aren't these models only sufficiently accurate if you use the
dimensions in the models to build an actual yagi, if the boom is non
conducting? Is it not true that if the boom is conducting you cannot rely on
the model dimensions?

Not so!
This method only applies to surface type corrosion materials that when
formed protects against ingrained corrosion.
Aluminum and copper are types where corrosion is halted after surface
corrosion. Anybody who has had an old car knows that rust can travel under
so called protective surfaces
This analysis was used with succes in court in the case of using aluminum
wiring in stead of copper wiring. The vital point was
that both of these materials formed a protective corrosion coating
that could not be undermined if the inter pressure point was not open to
corrosion penetration.

When I recently started out on HF these two antennas seemed to be obvious canditates given the dimensions of my rear garden. I started out with an L of similar dimensions to those quoted by the OP, and later tried a doublet (close to half G5RV) with an open wire feeder which ran rings around the L.
Not a fair comparison by any means outside the context of my garden and given that the radial system for the L was 4 wires on the ground no more than 25 feet in length.
My next step is to try a doublet of twice the length with the excess wire at each end being guyed in various directions as necessary .
Have any of you experience of this and particularly of optimising what will probably be an assymetric assymetric antenna?

http://www.cebik.com/scales.html

"Although I have omitted details--since they may vary widely--the general
principles separating the three mounting systems should be clear. The first
version uses a non-conductive plate or other means of insulating and
separating the element from the boom. If the separation is sufficient, the
boom has virtually no effect upon the element. In such cases, one may use
modeled dimensions directly, since the model (whether NEC or MININEC)
presumes that the elements are isolated from unmodeled conductors. An
alternative to the insulating plate is, of course, to use a non-conductive
boom. This technique permits through-boom mounting for the element, but with
no change of the effective length of the element."

(Scaling and Adjusting VHF/UHF Yagis L. B. Cebik, W4RNL)

So, I could use a metalic boom but make sure the elements are insulated, then the model is pretty much the practical design.

This means then that designing a practical antenna would be greatly simplified either by using a non conducting boom or insulating the elements.

I'm still unsure of point 3. But I assume that for a single wire that is made source in an antenna program, DE is a simple hertz dipole, the dimensions and the electrical parameters would be reproduced in a practical design cut to the dimensions as per the model - if the elements are insulated or the boom is non conducting.

3789. How do I feed a wideband VHF yagi with a balaced DE with unbalanced coax?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-10 17:24:47 UTC
From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <2irjq0FpsitoU1@uni-berlin.de>
Source record: 93644

The yagi is centered on 159 Mhz with a bandwidth of 6 Mhz.

The feed is 50ohm coax.

The DE is a simple hertz dipole. It's electrical parameters at the resonant frequency are R 50.9 J + 10.3.

What kind of balun would you use? TIA.

>>reflected voltage involves a reflection coefficient of 1.0 at your virtual short.
>>Steve's reflection coefficient is the *physical reflection coefficient*, not the
>>virtual reflection coefficient and is NEVER equal to 1.0.

Cecil, I'll give you an example below, taken from your own 1/4 wl transformer
analysis, that proves a virtual reflection coefficient can equal 1.0.

>Now I see your problem, Cecil, and that is because you still don't understand
>why a reflect ion coefficient of 1.0 IS established when two waves equal in
>magnitude but of equal and opposite phase occur at the match point. If the two
>waves are of unequal magnitude the coefficient is simply less than 1.0. So I
>repeat for emphasis, it matters not whether the reflection is established by
>physical or virtual means. This is another error in Steve's article. He disputes
>this established fact, saying incorrectly that a physical short is required to
>establish reflections--totally wrong.

In your 1/4 wl transfomer analysis we have Pfwd total = 133.33 w. 33.333 w of
this incident power was reflected, even though in originally separate, but
eventually integrated waves to sum to 33.333 w. The originally separate, but
eventually integrated voltages were totally re-reflected at the match point. I
know that you agree that all reflected waves are totally re-reflected at the
match point. How do you suppose those waves became totally re-reflected? It can
be accomplished only if the aggregate reflection coefficient is 1.0.
Consequently, in the steady state the input of the 1/4 wl transformer presents a
reflection coefficient of 1.0 to the integrated sum of individual reflected
waves. The separate forward and reflected waves that appear in your analysis
occur separately only during the transition period from the initial state to the
steady state condition. Can't be any other way, Cecil. Believe it!

Oops! Time to wipe the CRT clean... Henry wants to discuss a SHORTED
stub...reset. end. stop.
My original comments hold. Harmonics are "reflected" or however you
want to look at the fact that they don't make it to the "matched load".
...... Unfortunately, I continue...

Assuming Cecil's comments will be valid if I swap the 1xF (1/4W) and the 2xF
(1/2W) comments, I proceed...

>
> If the stub is 1/4WL,
[... RESPONDIND as though this was the 1/2W remark...]

At the mouth of the stub, they

In my mental model, a hi Z across the line.

>
> Absolutely nothing except superposition and interference happens at the
> mouth of a stub. All the reflected action happens at the physical open
> circuit. Virtual impedances are only a V/I ratio and CANNOT cause
> reflections. Absolutely no reflections are happening at the mouth of
> the stub (unless a physical impedance discontinuity exists there).

\\ Nit alarm on\\ (Though I consider this a clarification in an attempt to simplify the explanation and remove the extra complexity added by the double terms) I consider superposition and interference to be the same thing. Superposition is the addition of two quantities (voltages ot currents). They can be of similar sign or different. If they are closer to 'in-phase', then they add to a greater value and if they are closer to 180 degree phase difference, then they add to a smaller value. You can call that "algebraiclly add" if it makes you feel better.
That is, a +1 and +1 _add_ to +2. A -1 and a +1 _add_ to 0.0
\\ end nit alarm \\

This IS a correct way to look at it. Think of the "main" line" (the one going to the "matched load" above) as being the thing which is "added to" the shorted system. Since it is added to a low Z point (on this high VSWR line), little goes down that path to the desired load. Any 50 ohm "thing" put in parallel at the point of the lowest voltage of the standing wave, sees a low/zero voltage, therefopre nothing goes there.

>
> Consider this. If a stub really presented an infinite impedance, you could
> simply remove it and nothing would change.

At the fundamental (_OPEN_ 1/4W stub, remember) this IS TRUE.
Are you saying that the 1/4W _shorted_ stub addition or removal makes a BIG difference at the fundamental -I think not, or you still talking about the 1/4W _open_ stub which kills the system at the fundamental when added.

An application just means that the _applicant_ believes it is patentable.
If the examiner finds sufficient prior art, out it goes. On the other hand,
there is something to be said for applying several older ideas to a new
problem and making the _combination_ patentable.

This sounds like false theory. He is implying that a distributed
inductor opposes a difference in current along its length, no?

The RF current in the distributed inductor can be different along its
length, modeling shows that, but this is AC and it is _always_ opposing the
changing AC (in this case RF) current at any point of the coil. That's what
inductors do. I can't get this to extend to opposing different AC currents
along the length of a long coil. If there is enough field from one end of
the coil coupling to the other end, then a falling field at the first end
tends to oppose a change in the current at that end as well as at the other,
but that's an opposition to a change in instantenous current, which will
increase inductance, not the AC current magnitude...

> "What I found was that for any smaller antenna, if you place a
> load coil in the middle you can normalize and make the current
> through the helix unity; that is, you can maximize it and
> linearize it," he added. <<

I can't get "Linearize" to work. Does he mean, "vary linearly along the
length"? "Normalize" and "unity" are pretty obsure as well.

Guess I'll wait for the movie to comeout.

I agree the results are identical - It matters within the analysis but it
doesn't matter to the outcome. You and Steve get the same outcome. The
things you are arguing over is what happens inside the model each of you
is using.

> Now I see your problem, Cecil, and that is because you still don't understand
> why a reflection coefficient of 1.0 IS established when two waves equal in
> magnitude but of equal and opposite phase occur at the match point.

Walt, please listen to this again. I understand why a reflection coefficient
of 1.0 is established in your model. I understand why it is impossible for a
reflection coefficient of 1.0 to exist in Dr. Best's model. It is now up to you
to understand why it is impossible for a reflection coefficient of 1.0 to exist
in Dr. Best's model. A reflection coefficient of 1.0 also does not and cannot
exist in an S-parameter analysis of the following example.

> Cecil, we don't need to argue the conditions concerning S-parameter analysis,
> because I've put my finger on the problem you're having with this entire
> discussion, that is you're (and Steve's) unwillingness to understand that wave
> interference can establish a reflection coefficient of 1.0 without any physical
> means.

It is IMPOSSIBLE to establish a reflection coefficient of 1.0 in an S-parameter
analysis of the following:

100W XMTR---50 ohm line---x---1/2WL 150 ohm line---50 ohm load

The reflection coefficient at point 'x' in Dr. Best analysis is ABSOLUTELY
CONSTANT at 0.5. It NEVER changes from 0.5. It is always (150-50)/(150+50)
equals 0.5. It NEVER becomes 1.0 as it does in your analysis. A reflection
coefficient of 1.0 is ABSOLUTELY IMPOSSIBLE using an S-parameter analysis of
the above configuration.

Using an S-parameter analysis, a reflection coefficient of 1.0 DOES NOT exist
anywhere and CANNOT exist anywhere. Until you accept that fact, you will continue
to be confused.

Let me say it once again: THE "REFLECTION COEFFICIENT" THAT YOU ARE USING HAS
A DIFFERENT DEFINITION THAN THE "REFLECTION COEFFICIENT" THAT DR. BEST IS USING.
IT IS IMPOSSIBLE FOR DR. BEST'S REFLECTION EVER TO EQUAL 1.0. Dr. Best's rho is
NOT equal to and is NEVER equal to SQRT(Pr/Pf). Why is that so hard to understand?

I don't worry about the boom. It's effect on the antenna is small. All
my booms normally are metal.
Is it not true that if the boom is conducting you cannot rely on
> the model dimensions?

I don't think it is to any great degree worth losing sleep over. I built
the eznec NBS yagi for 6m, and used those dimensions, using my own
construction techniques, and it came out nearly perfect as per the
model, and modeled results. To me, you are taking a simple task, and
overly complicating things by insisting on utter perfection in element
diameters, boom, element mounting, etc. For a VHF receive 3-4 el yagi,
it's just not *that* critical. When I built a marine yagi, I paid little
attention to exact element dia, mounting , boom, etc. I used coathanger
wire welded directly to the copper tube boom. I didn't try to optimise
the lengths, etc. In fact, this was waaaay before I'd ever seen a
modeling program. It still worked just fine.

Save your energy, Walt. An S-parameter analysis does NOT allow for virtual
reflection coefficients. Virtual reflection coefficients DO NOT EXIST and
CANNOT EXIST in an S-parameter analysis. I don't know how to convey that
fact to you any stronger than I already have. Virtual reflection coefficients
are completely irrelevant to an S-parameter analysis. Virtual reflection
coefficients simply do NOT exist within the S-parameter math model.

> Consequently, in the steady state the input of the 1/4 wl transformer presents a
> reflection coefficient of 1.0 to the integrated sum of individual reflected
> waves.

Walt, virtual reflection coefficients simply don't exist in an S-parameter
analysis. Therefore, in all the examples discussed, reflection coefficients
of 1.0 are COMPLETELY IRRELEVANT to any discussion involving S-parameters.
Reflection coefficients of 1.0 DO NOT EXIST in an S-parameter analysis of a
matched system involving 50 ohms and 150 ohms. s11 is the reflection coefficient
looking into port 1. It is fixed constant at 0.5 and doesn't chance no matter
what the conditions. Your assertions are simply irrelevant to an S-parameter
analysis.

I don't think it matters much what boom you use. Being at right angles
to the elements, the boom should be nearly "invisible" to the antenna.
Even if it's metal, Even if the elements are directly connected to the
boom.
Sure, there will be minor differences, but for your task, I don't think
it's worth worrying about. I sure don't. I'm not *that* picky.
>
> 2 For a VHF yagi in the clear you can assume freespace.

Yes. For all practical purposes...
>
> 3 A simple straight wire in your model that is made source is DE and
> is treated as a simple hertz dipole by the program. So the values given for
> R and J are the values you would measure having a hertz dipole as DE.

Yes. Normally will end up a fairly low impedance, unless you space the
elements for a appx 50 ohm feed. NBS yagi's will have a fairly low
feedpoint impedance. Thats why I prefer just to use a boom grounded DE,
and use a matching device. I almost never use a split driven element
unless the yagi plans call for a 50 ohm feed due to the element spacing.
My cushcraft A4S is of this ilk...

> This is true for the model and would be fairly accurate if the boom was
> non conducting and reasonably in the clear in the practical design.

Again, even if the boom is conducting, I don't think it's worth worrying
about..It doesn't make that much difference. Or to me anyway...

>
> 4 It is easy to scale for frequency in antenna programs.

Yes.
>
> 5 It is fairly easy to alter element diameters in antenna programs and to
> obtain a redesign that maintains the original performance characteristics.*

If you simply rescale, the results should be the same. All dimensions
are rescaled. Of course, you can doodle with the program and redesign..
>
> It seems to me that if one is prepared to use a non conducting boom, a
> hertz dipole as DE, then the model is pretty much the practical design.

I think it is good enough, no matter what the boom is...
>
> Not sure about impact of a balun or the feedline.

If you use a split driven element with a 50 ohm feed, you need a 1:1
balun, or equal choke, or whatever...

What has happenned is that I, who know little of the art, am relying on whoever condescends to make a comment. And comments so far have tended to highlight how unsatisfactory it is taking a model and bulding a yagi on the dimensions. There seems to have been a desire to point out to me how impossible a task it is to build a decent antenna unless one factors in alteration of boom size and element diameters. Technically these comments are correct, you cannot expect to get the same antenna performance if these things are ignored and I feel I've been concentrating on these details for fear of not doing enough. But on the other hand, will the difference on receive amount to much whether elements are insulted from a boom or not . Probably not eh.

>outdoor environment.

I've seen square, hollow rods made of fiberglass. Should work
reasonably well as long as you drill it carefully, cap the ends to
keep and wind out, and paint it afterwards to protect the resin from
solar UV.

Sorry, a shorted 1/2WL stub exhibits a short at the fundamental frequency
and an open when it is 1/4WL at 1/2 the frequency of the first. Same
principles apply.

>>Absolutely nothing except superposition and interference happens at the
>>mouth of a stub. All the reflected action happens at the physical open
>>circuit. Virtual impedances are only a V/I ratio and CANNOT cause

So do I. I probably should have said superposition/interference, which logically
equals (superposition AND interference) since ONE AND ONE = ONE.

>>Consider this. If a stub really presented an infinite impedance, you could
>>simply remove it and nothing would change.
>
> At the fundamental (_OPEN_ 1/4W stub, remember) this IS TRUE.
> Are you saying that the 1/4W _shorted_ stub addition or removal makes a
> BIG difference at the fundamental -I think not, or you still talking about
> the 1/4W _open_ stub which kills the system at the fundamental when added.

Any stub that presents an infinite impedance should be able to be removed
and without anything changing. You have an infinite impedance before the removal
and you have an infinite impedance after the removal, so nothing changes when
you remove the stub. (Hint: Devil's advocate reasoning applied) Of course,
something changes when one removes the stub - that's the entire point. There
are forward components and reflected components flowing in and out of a stub.
That's why removing it changes things.

>
> I can't get "Linearize" to work. Does he mean, "vary linearly along the
>length"? "Normalize" and "unity" are pretty obsure as well.
>

He means that a very electrically small monopole can be designed so it has no current maximum: the current does not vary in magnitude with height. The current value is the same along it's length.This is common for top hat monopoles which are less than 1/30 wave in height.

The issue arises in the Vincent discussion because the electrical length of the antenna is far in excess of the height, so the current changes--unless you distribute additional inductance and capacitively truncate at the top.

Because the antenna is electrically long and physically short, it has a higher feedpoint resistance, although the tradeoff of higher ohmic losses to higher rad resistance gives, at best, a wash on gain.
It is, in effect, a short, slow wave antenna.

Monopole limits: At 1/30 wave height, the bandwidth can be on order of a few percent or less, with -2 dBd or so. I have worked with such antennas for some time. If you increase heights to 1/15 wave, the increase in bandwidth can be dramatic.

The problem is that broadcast antennae need reduced height--but don't need the many-percent bandwidth. They also have arcing issues from high voltage.

The problem is that commercial and military applications (such as cell phones) need multiband or wideband--and not the modest bandwidth.

The problem is that RFID doesn't have a size and gain problem, but an impedance problem.

Thus the 'revolution' is somewhat small in population....But hams need modest bandwidth and low height. Hence a potential niche.--if you have room for a ground plane.

Is there really a market for short , single band, ham monopoles? Understand that for a few more feet in height, you can get an MFJ multiband vertical--without a radial system.

>exist in an S-parameter analysis of the following example.

Why do you keep insisting on an S-parameter analysis? What good are you accomplishing with it ? And speaking of Steve's model--he shows it in his Fig 5 as a simple T-network as used in most antenna tuners. The effect at the input of the network is no different than in a stub model or a 1/4 wl transformer model. You can't rely on 'different models' to explain away the problem. When properly adjusted to match the output to the input in his T-network the reflected power reaching the input is totally re-reflected. This results only from a reflection coefficient of 1.0. Saying that it is impossible for a 1.0 to exist in Steve's model is simply not true. Steve simply doesn't understand the wave mechanics involved here.

>> Cecil, we don't need to argue the conditions concerning S-parameter analysis,

>
>100W XMTR---50 ohm line---x---1/2WL 150 ohm line---50 ohm load

It's true that the physical reflection coefficient is 0.5. How then do you account for ALL the reflected energy being re-reflected to the load? The fact is that a reflection coefficient of 1.0 is also established there by wave interference. You really must come to the grips with the fact that a reflection coefficient of 1.0 can be established by wave interference. You are now the one who won't budge.

>The reflection coefficient at point 'x' in Dr. Best analysis is ABSOLUTELY

>
>Let me say it once again: THE "REFLECTION COEFFICIENT" THAT YOU ARE USING HAS
>A DIFFERENT DEFINITION THAN THE "REFLECTION COEFFICIENT" THAT DR. BEST IS USING.
>IT IS IMPOSSIBLE FOR DR. BEST'S REFLECTION EVER TO EQUAL 1.0. Dr. Best's rho is
>NOT equal to and is NEVER equal to SQRT(Pr/Pf). Why is that so hard to understand?

I haven't seen anything in Steve's paper that shows he's using an S-Parameter, can you show me where? Not that it would make any difference in the outcome.

In addition, referring to your paragraph immediately above, where did you get the idea that I said Steve's rho = SQRT(Pr/Pf)? Cecil, that's simply SWR, not rho.

At this point, Cecil, if you are still unable to accept the concept of establishing a reflection coefficient of 1.0 through wave interference then there is no use of continuing this discussion. It will never go forward until you do. I know there are others on this rraa who agree with you, but there are many more who understand the concept and agree that it's true.

> Probably not eh.

It does make a difference, but I don't think it's anything that would ruin an antenna. Lets say "perfect" design shows 9.4 dbi. Lets say "not quite perfect" design shows 8.4 dbi gain. Hardly noticable in the real world. Most consider 6 db to equal an S unit in theory as an example...When building my 6m yagi, "three element" I copied the eznec NBS specs exactly as far as element lengths and dia. The dia was 1/2 inch , which was easy to copy using 1/2 inch copper tubing. I gave no real thought about boom size or type, DE type, etc. I built the antenna per specs using welded to the boom elements, and welded to the boom one piece DE, matched using a simple gamma match. The antenna is all one piece including the boom. If I had used a split DE, I would have still used the same lengths...Anyway, I built it and tested it using local stations as signal sources. The gain and f/b "seemed" to be almost exactly as modeled, as well as I could measure. IE: the modeled f/b is appx 10 db. Thats about what I got. The forward gain seemed to be about right on also. "appx 9.4 dbi".
The easy way out for you, would be to get an existing 2m yagi, and simply trim the elements. You could rescale in the model program to tell you how much to take off. Sure, the spacings will change slightly, but again I bet it won't be noticable. If anything, being the spacing will actually slightly increase in wl, the gain "could" actually increase slightly. I bet it doesn't drop much... The modeling program would give you a good idea of what to expect from it. MK

BTW, if you rescale a 2m antenna, it will also rescale the spacing. So
in order to be accurate, you would need to respace the rescaled shorter
elements to match the old spacings. "After rescaling". Fairly
simple..That would give you a decent idea what to expect from the
modified antenna. MK

As a test I first rescaled the eznec 50 mhz NBS yagi to 146 mhz. I used
6-7-6 as the demo segment numbers. You are limited to 20 in the demo.
This kept the source in the middle of the DE..I ran it through the mill
and got 9.63 dbi gain, and 9.35 f/b. I then rescaled that antenna to 159
mhz. I then set the element spacings back to the 146mhz version specs.
Through the mill, and got 9.68 dbi gain, and 7.73 db f/b. About as I
expected...It would still be a good antenna. f/b is not much of an issue
for your needs in general...Thats more of an HF thing...You want gain
for local VHF. The chances of someone on your backside causing QRM are
fairly low... Find a 3-4-5 el 2m antenna, whack the elements down a tad,
and you'll be done with it. Well, unless you still wanna try building
one. It's easier to make a decent working yagi than you think, I
think...All that worrying about utter perfection will drive you to the
rubber room. :/ You would have to see about a 3 db difference in
performance to start really being noticable. Or my guess anyway on 159
mhz... MK

Yea, but in the practical sense, it does not change anything at the
fundamental (desired) frequency [[high Z stub, power still to the load]].
It's only when you consider the harmonics, if they are there, that anything
important changes, right. So I'm puzzled why you included that part in your
comment.

//nit alarm on//
It's not a J-POLE. It's a J antenna. The J-POLE was a commercial antenna possibly by Cushcraft some time ago. It was a pole with several Js stacked vertically on it for gain. The J antenna goes back as far as my handbooks do at least the 40's.
I'd call this an end fed half wave. What's the matching device? A quarter wave shorted stub.

There use to be a program available written by Gunter Hock, DL6WU, that
was for designing VHF/UHF yagi antennas. It took into account boom type
and size, element size, bonding methods, etc.. The original program was
written in BASIC. For my own use, I converted it over to a JavaScript

driven web page. If you are interested I just posted it on the web at http://www.k7mem.150m.com/Electronic_Notebook/antennas/yagi_vhf.html. Maybe this is the kind of thing you are looking for. The original BASIC source code is available.

I only started this web site a week ago so don't expect everything to work completely. There are several known links that really don't go anywhere yet.

Did you have to support the ends of the conduit (e.g. a wire from the
tower top) at all? I've heard/read that the PVC conduits can tend to
droop progressively with time - any sign of that in your antenna?

Source record: 93522

You didn't mention if this would be used in some sort of transmitting application or not. Heck, for just listening across a 6mhz spread, I'd just connect the coax and not worry about it.

>Any stub that presents an infinite impedance should be able to be removed
>and without anything changing. You have an infinite impedance before the
>removal and you have an infinite impedance after the removal, so nothing
changes. There are forward components and reflected components flowing in and
out of a stub. That's why removing it changes things.

Is it because energy is stored in the stub? If the impedance is infinite then
no power dissipation is removed from the system. Something is dynamic in
nature in this example because if you remove an infinite impedance, nothing
will happen. Could the change be due to the fact that the stub is in the near
field of the antenna and subject to induced rf currents? If this were the
case, then removal of the stub would change things.
If the stub presents an infinite impedance, with no external influences,
removing it should have no effect. If the stub were replaced with a quality
parallel resonant LC circuit in a shielded box, would removing it make any
difference? I don't know, I am asking.

If you are around any oil rigs you may be able to find some old pump rod. This rod is fiberglass, one inch in diameter with a large metal connector on each end. Just hack saw the ends off and you have about 20 feet of very rigid fiberglass rod. It is easy to make booms of 6 to 8 feet with no droop at all so a shorter boom would be even better. If you find some after you have cut it to length give it a good coat of paint just to keep the fiberglass slivers down.

> How do you put capacitors in? Is this a good slow wave solution?

CCD antenna use capacitors in a distributed way to cancel the inductance. They are commonly used in 1 wave dipole configurations. They have higher feedpoint impedances than 1/2 wave dipoles and they have 3 dB gain when fully stretched. Their pattern is figure 8, like a 1/2 wave dipole.

The Vincent antenna could use such an arrangement to emulate a 1/2 wave monopole CCD (that is, a 1 wave dipole) where the 1/2 wave electrical length is wound into a helix along the height.. In any case, there are a number of ways of doing this. In my opinion, this is not new, if that is the case.

I suspect that Vincent has a number of combinations of arrangements, depending on the desired height above 1/30 waves.

Remember: these are not efficient antennas; they are slow wave antennas. Put lots of power into them and they will heat up; arc; and melt. They trade gain against efficiency. They are not multi or wideband.

I would be very interested to know how hot a Vincent antennas when running 1500 watts continuous for an hour....If it's hot it's not efficient.

There you go - that's the secret sauce. It wasn't obvious
from the catalog photos that the dipoles were inclined at
an angle.

Good info, Richard.

> droop progressively with time - any sign of that in your antenna?

The plastic conduit is about 10 feet long and the elements are for 220 mhz
made out of stainless steel 1/8 inch welding rod. The driven and reflectors
are the quagi design. Eight elements total as in one of the ARRL handbooks.
The diameter is about one inch conduit size . That makes it about 1.5
inches or more outside diameter. There is a slight droop but not very much.
There is no support other than the way I mounted it in the middle to the
mast.

At 2m, yes, especially if it's a decent broadband design, at 432,
definately no, even if broadband. The shielding from the boom is
significant at 432.

I think you should consider wood if you properly 'weatherize' it. Not
sure of which plastic is used, but there are plastic 2x2 posts used to
support newly planted trees that may fit the bill also, check your
local Lowe's/Home Depot/Nursery to see what they have.

Good luck,
Howard

Just to be precise: it is NOT resonant!! Resonance requires that there
be a zero value for the j term. The +j10.3 indicates your antenna DE is
a little long for the measured frequency.

You both get the same measurable forward and reflected powers,
forward and reflected voltages, and forward and reflected currents.

> Why do you keep insisting on an S-parameter analysis?

Because that is essentially what Steve used and it works. It has
worked for decades. Please download the HP AN 95-1 and see for yourself.

> When
> properly adjusted to match the output to the input in his T-network the
> reflected power reaching the input is totally re-reflected. This results only
> from a reflection coefficient of 1.0.

Only in your model, Walt, not in Steve's. Reflection coefficients of 1.0
are INVALID in Steve's quasi-S-parameter model.

> Saying that it is impossible for a 1.0 to
> exist in Steve's model is simply not true.

Yes, it is true, for the configurations discussed so far. The ONLY time a
reflection coefficient of 1.0 exists in Steve's model is for a *physical*
short, a *physical* open, or a *physical* pure reactance. In Steve's model,
virtual stuff is invalid.

> It's true that the physical reflection coefficient is 0.5. How then do you

> interference. You really must come to the grips with the fact that a reflection
> coefficient of 1.0 can be established by wave interference. You are now the one
> who won't budge.

You are asking me to budge away from the rules of an S-parameter analysis?

Sorry, Walt, virtual reflection coefficients are INVALID in an S-parameter
analysis like Steve is using. The s11 reflection coefficient that Steve uses
is defined as the "input reflection coefficient looking into port 1 with
the output port terminated by a matched load." Since there is no such thing
as a Z0 = 0 or a Z0 = infinity, there is no such thing as a reflection
coefficient equal to 1.0. The reflection coefficient, s11, that Steve is
using can *NEVER* be zero or one - *NOT EVER*.

> I haven't seen anything in Steve's paper that shows he's using an S-Parameter,
> can you show me where? Not that it would make any difference in the outcome.

His reflection coefficient is (Z2-Z1)/(Z2+Z1). That is identical to the S-parameter reflection coefficient, s11. It is a constant and never changes to 1.0, no matter what happens to the reflected power. Dr. Best simply doesn't use virtual reflection coefficients. Using virtual reflection coefficients in an S-parameter analysis is *INVALID*, i.e. they simply do not exist.

> In addition, referring to your paragraph immediately above, where did you get
> the idea that I said Steve's rho = SQRT(Pr/Pf)? Cecil, that's simply SWR, not
> rho.

Let's take the 133.33W forward and 33.33W reflected example. rho equals the square root of (33.33/133.33) = 0.5. That's not SWR, Walt. SWR cannot be less than unity. That is indeed the physical voltage reflection coefficient.

> At this point, Cecil, if you are still unable to accept the concept of
> establishing a reflection coefficient of 1.0 through wave interference then
> there is no use of continuing this discussion.

I accept the concept of a reflection coefficient of 1.0 for your model, Walt. But a reflection coefficient of 1.0 is simply NOT allowed in the quasi-S-parameter analysis that Steve uses. The S-parameter analysis works and has been used for decades but an s11 of 1.0 simply never happens (except at a short or an open). The reflection coefficients in an S-parameter analysis and in Steve's analysis are ***PHYSICAL***. They are ***NEVER*** virtual. I'm sorry if that upsets you. I don't know what else to say.

Some people believe that there is no current flowing into or out of a
1/4WL shorted stub. But all they have to do to change their minds is
measure the current through the short at the end of the stub. It is sky
high. The SWR inside a 1/4WL shorted stub is near infinite, i.e. the
square root of Pr/Pf inside a stub is near unity.

Exactly! Therefore, the infinite impedance at the mouth of a stub
is a virtual impedance, not a physical impedance. The physical
impedance exists at the end of the stub where all the reflections
are taking place. Reflections occur only at a physical impedance
discontinuity.

Yes, but only after making a round trip to the short or open at
the bottom end of the stub. V/I ratios don't cause reflections.
Only physical impedance discontinuities cause reflections.

Reg

I've been trying to learn how to make baluns for the past few weeks. I
really appreciate your program. I downloaded it this morning and have been
thinking about it since then.

I had thought that I'd be restricted to using low loss insolution for the
wires on the baluns I've been building. I tried using 3 paralel wires from
a computer ribbon cable, but the losses have been way too high (at 137MHz)
Also, I would like to bild some 1:1 baluns with ferrite cores but cant
find a way to build them within my capability.

Thanks for the great program

Jerry

That's true, in the sense that yagis "want" to work. Even when elements drop off completely, they will continue to "beam up" in the forward direction.

However, this isn't an absolute guarantee that you can forget about correcting for element diameter and boom effects. If all the directors are too long, it can tip the first (longest) director into behaving as a reflector, and then the whole beam can reverse direction at the high end of its frequency range. Now that, you would notice.

>When building my 6m yagi, "three element" I copied the eznec NBS specs
>exactly as far as element lengths and dia.
...
> I gave no real thought about boom size or type, DE type, etc.

On 6m you probably don't have to, because boom corrections on that band are very small for most reasonable mounting methods. The reason why it worked is because you *did* scale the element diameter.

As so often, whether something "matters" depends on how much satisfaction you get from doing the best you can.

Regarding Richard's multiple musings, let's cut to the chase.

Richard, you've thought yourself a long way into this problem, and much of your thinking is good. But now you're spinning your wheels and getting no further. What you need now is to DO something!

1. Decide roughly how long you want your beam to be.

2. Go to a good timber merchant where they'll let you select a straight, knot-free length of square timber, about 35mm square. Pick up a packet of small staples and a pot of varnish.

3. Go to a farmer's merchant (lots of those in central London) and buy 10 metres of heavy galvanized fencing wire.

4. Varnish the boom. While the varnish is drying, go to www.cebik.com and pick an OWA (Optimized Wideband Antenna) design that will fit on the boom, and is designed for a direct 50-ohm feed.

5. Run Cebik's element dimensions through ELE.EXE to re-scale them to your frequency and your element diameter. If you won't be able to measure the SWR, make the driven element length half-way between the

lengths of the reflector and the first director.

6. Now switch off your computer, and don't come back until you've actually BUILT a yagi. You don't need advice for that - you NEED to work it out for yourself.

(Hints: Watch your thumbs when you staple those elements to the boom. You'll have to work out a different way of supporting the driven element, which has been cut in the middle... any Blue Peter [*] graduate would know how.)

[*] British children's TV show, notorious for its construction projects. "If your mother allows you to use sharp scissors, then cut a leg off the kitchen table and... "

There are now many different programs called "dl6wu-something.bas" out
there on the web... but DL6WU didn't actually write any of them.

The master copy of the program that Martin is using is on my 'VHF/UHF
Long Yagi Workshop' page. It was originally written by KY4Z and W6NBI,
and AFAIK it is still the only one that DL6WU has personally checked
against his original tables and graphs. For that reason it is guaranteed
to be maintained for the indefinite future.

However, the DL6WU yagis are not suitable for the OP's original request
for 5/6 elements, because these are all "long" yagis with a minimum of
10 elements.

RE: Post below from May 20, 2004

Wouldn't a "non-radiating" feedline in the field of a radiator also distort the patterns of that radiator? Any conductor can do that, even if it is not a feedline. NEC-2 models of FM broadcast transmit elements (and test range patterns) show this clearly.

Paper 6 at http://rfry.org shows the free space patterns that the element arms of a rototiller FM broadcast transmit antenna develop if they could be driven from internal power sources -- and then the effects of adding the element stem, mounts, feedline, and some nearby tower structure. The patterns can get very skewed, even though the only radiators getting power via a metallic path from the tx are the element arms themselves.

Hello--

I've received about 2 dozen e-mails on this subject. Prior to this, I communicated with Mr. Vincent early on 9 July and offered him the opportunity for scientific and objective independent testing. He declined due to a test already ongoing at a facility that I feel is also capable of such testing (you may ask Mr. Vincent if you wish).

My scientific interest in this topic is exhausted. I pose the following for those interested in what is possible, and what has been done, along the lines of distributed loading of helix monopoles. I invite you to investigate the prior art for yourself.

I have not seen Mr. Vincent's design, but based upon his PR statements, it appears to be a loaded helix monopole with a CCD-like arrangement for neutralization. The design, of course, may be different and novel, although I am not of that opinion, based upon the 3 reports published in the popular press. In the absence of knowledge, it is impossible to fully assess. Still, there is value in knowing what has been done and what is possible.

The prior art is rife with distributed loading of monopoles to extensively shorten them.

Here is a prior art method that will gives a few percent bandwidth and about -2 dBd for less than 1/15 wave height. I invite you to experiment for values and placements:

* Take a half wave of wire (approximately);
* Wind it into a helix of about 10^-3 waves diameter (or less);
* Place an inductive load half way up;
* Add at least 2 and up to 6 capacitors at distributed points along the helix length;
* If you wish to truncate the current at the top, then add a small end cap hat;

Essentially this is a shrunken 1 wave dipole manifest as a 1/2 wave monopole, using CCD (distributed capacitors) to neutralize the inductance. (remember: not all cacapcitors need be discrete components). Helical designs originated with Harold Wheeler more than 50 years ago. CCD articles have predominantly appeared in ham magazines in the 70's and 80's, although the original invention is (I believe) British and over 40 years old. There are many relevant patents, all expired to my knowledge.

This design approach will 'linearize' the current (slow he wave) and do a pretty good job. A shrunken 1/2 wave monopole does better than a shrunken 1/4 monopole. When you compare it to a full-sized 1/4 wave monopole it will do well

at a specific frequency.

It is an interesting question whether the relevant comparison should be to a 1/4 wave monopole or a 1/2 wave monopole. Such shrunken designs are 1/2 wave equivalents, not 1/4 wave equivalents. They will look much worse in performance compared to full sized counterparts. A 1/4 wave monopole is not a counterpart, although in a practical sense it is a much used antenna which one might seek to replace and thus compare to.

HOWEVER for such a shrunken design--

* It will be moderate to narrow band;
* It will trade gain for efficiency and is NOT efficient;
* It will run hot in continuous-on applications with moderate to high power.

Gain is not efficiency. Sometimes efficiency doesn't matter, but gain does. Other times the heating from inefficiency will kill an otherwise elegant design option.

Mr. Vincent's original PR claims, to my recollection: high efficiency; good (broad) bandwidth; very low height.

These are not mutually, physically, attainable. I, and many others, have spent enough time to know. There is no reason to believe that Mr. Vincent has attained these. What he has appeared to have attained, to my limited knowledge based on published PR, is: moderate to low efficiency; modest bandwidth, and very low height. To my knowledge, Mr. Vincent has neither done an efficiency test nor a heating test.

In terms of applications, there are very few, besides some 'ham' and CB needs, where a single band, somewhat inefficient whip is desired. Midland has a nice compromise stick for CB'ers that's using some of these ideas and is two feet high. I like their design.

--Using a heavily shortened CCD type helix monopole in a broadcast app will lead to a fire. It is not highly efficient and the wasted power will manifest as heat. As little as 30 watts of heat in a confined area will start a fire or melt components if not properly dissipated. About a 1 dB loss to heat for 1000 watts power will produce well over 100 watts dissipated heat. Ergo, even a reasonably efficient antenna is potentially dangerous if high power is used and the heat is not properly dissipated. Mr. Vincent's design PR describes melted components in some of his design efforts. This indicates inefficiency in the design tested.

--Much of the world wants 'ground independent' antennas--not monopoles

-- Microwave applications are not single frequency, with few exceptions. Even PIFA (inverted F) solutions--which are extremely low height, lower than Mr Vincen'ts-- are multibanded.

--Much of the world wants multiband antennas, or wideband antennas, not modest passbands.

Nice site, I like the "white paper" approach as I prefer the info without
the glitter. I've only read a few items and I
quote: "This is a plot of the attenuation provided by the stub. You can see
that it provides about 32db of attenuation at 28.25Mhz. " I've noticed that
the literature I've purused indicates that stubs either attenuate or reject.
None say reflect! I don't want to get into a discussion of word definitions
becasue reflect and feject are close but attenuate is not in the same class.

A fellow ham sent me an email suggesting a use for a shorted
1/4WL stub that had not occurred to me before. Many hams have
static electricity problems with dipoles since there is not
a DC path between the poles. For a single-frequency dipole,
a shorted 1/4WL stub could be installed at the feedpoint to
drain off the static electricity without affecting the
performance much on the fundamental frequency. It would also
aid in the suppression of even harmonics.

They indeed do attenuate or reject. Reflections is the method by which
stubs accomplish the attenuation or rejection. If one is only interested
in implementing stubs, and not interested in how they work, one need not
deal with reflections. What one must realize, however, that the SWR inside
a resonant stub is as high as it can be. All the reflections take place at
the shorted or open end of a stub, i.e. at the physical discontinuity point
where rho = |1.0|.

I don't have any argument with people who say, "I only want to use stubs.
I don't care how or why they work." My argument is with people who falsely
describe how they work, e.g. "Since the impedance looking into a shorted
1/4WL lossless stub is infinite, no current flows into or out of the stub."
If that were really true, one could remove the stub without changing
anything. The net superposed current may be zero but the forward and reflected
currents exist there and can be very high values. In fact, I have melted the
insulating material at the end of a shorted coaxial stub due to high I^2*R losses.

Richard, my point was, your antenna will funtion better centered on the lower part of the band, using any wideband features the antenna has to work upward in frequency, not downward.

Since DX'g was your goal, why not take advantage of this feature? During summer months troposheric ducting provides some pretty amazing DX features in this band. In the states, it is common to for stations to copy traffic hundreds of miles away when this happens.

Best regards,

Jack Painter

yes, that works very nicely also. it does provide a dc ground for otherwise ungrounded antennas like verticals or dipoles providing a way for static build up to drain safely.

the harmonic is 'attenuated' in that the magnitude of it is reduced when the stub is in line. i look at it like you could replace the stub with a lumped filter at the same point so the term attenuation makes more sense than reflections or rejections... i don't really care where the harmonic goes, i want to know how much it is attenuated by so i can compare with other types of filters.

Thank you for the corrections. I will make the necessary adjustments on
my web page to give proper credit.

I only suggested this program to show that there are programs out there
that take the factors he described into account. He could design for 10
elements and then trim back the number of directors. This will get him
in the ball park. He could then describe it to a modeling program to
see how it stacks up.

Very effective way for monoband antennas. The improved version of this is the "Bazooka Balun" which besides above mentioned benefits acts as a balun. I used it on all my monoband antennas. Provides DC path to ground, harmonic supression, RF choke function and balanced to unbalanced feed point conversion.

Where is the bulk of the attenuation taking place, at/in the stub,
or as a V^2/R loss back upstream? (Not a trick question)

I do think the politicians would listen to the National Association of
Religious Broadcasters, or whatever they call themselves.

It's probably "dry" N2. It is used to prevent water absorbtion and O2 absorbtion of the RF. It can also be used to detect leaks and to keep out atmospheric water.

That's another good point. I think $30 bucks a month might attract alot of buyers to BPL, but it's still not low enough for cheapskates such as myself. I do think the likely number of buyers is researchable, but reporters don't always do research. Since the number is unspecified, I'll assume the BPL folk didn't bring up this fundamental issue in their press release.

The finanical press usually has a disclaimer at the end of their columns. Something like "Our columnist owns no stock or any other interest in the company". That's nice, but it would be more informative to the reader if the disclaimer said "Our columinist has done no research for this column beyond reading the press releases of the company".

I know they work! One of my reasons for asking the question is I've not found any mention in the literature of where the "attenuation/rejection/reflection/filter residue" goes.

Something I found:on Cadweld notes which is Thermit:
Hi.

Despite several postings suggesting the words `exothermic' and `welding' be added to the TT word filter, I ordered some CadWeld ONESHOTS for use on ground rods. A few people have asked about how they work and I have some advice for anyone wanting to use one, so a brief posting is in order, IMHO.

Anyway, they work fine. They are more expensive than clamps, but provide a better connection and don't require the purchase of extra anti-oxidants, grease, etc. As an added bonus, there's a great fireworks show when they go off.

A few points to consider: First, BUY THE CADWELD-SUPPLIED IGNITION TOOL. A flame simply won't launch these and most consumer-oriented flint igniters don't project the spark far enough to enter the mold and ignite the material.

Second, if you get the kit for two wires to one rod, try and install it such that you have ONE wire passing through the mold to the next connection. I didn't and the process blew one of the wires out of the mold before it could weld. In any event, secure the wire from movement before lighting up.

Third, if you need to mail-order, I've had excellent results with The RF Connection (email: rfc@therfc.com). I ordered three kits, and because I didn't have the CadWeld lighter, I needed to add some material from the third kit to the second to achieve orbit. I mentioned this in an e-mail to rfc and they're having the warehouse ship another package of weld material. That's excellent customer service, as far as I'm concerned, especially since it would not have been unreasonable for them to say that I didn't follow the instruction, so tough noogies.

Hope that helps anyone interested in exothermic welding and didn't offend anybody who wanted the subject BANNED from the reflector.

73, kelly.

A 4:1 toroidal balun will also do the same thing -
provide a DC path between conductors.

Source record: 93568

you can look at it various ways.
1. the wave traveling wave analysis... the harmonic goes down the stub, reflects back, and when it gets back to the transmission line it is 180 degress out of phase with the next cycle so it cancels it at the junction... therefore there is no harmonic to propagate down the line past the junction. this of course will raise the hackles of the anti-reflectionists who will then say there is also no harmonic left to propagate down the stub which means there is a virtual short at the junction, but no way to generate it since nothing can be there to go down the stub.

2. the power analysis. power goes in, power comes out, it all reflects back and forth until the energy becomes infinite and the amp blows up... but of course energy is conserved and momentum must go somewhere so the stub probably walks across the table with each wave reflection.

3. the sinusoidal steady state analysis. this takes the stub and transforms the shorted impedance at the far end back to the junction and then does all calculations as if the real short existed at the junction.... this will of course annoy the reflectionists who will point out in never ending detail how you can't explain tv ghosts, radar, or other transient phenomena this way... of course by assuming the sinusoidal steady state at the start you exclude those systems from this type of analysis, but that won't stop the protests.

4. the s analysis... who know what this will say except cecil who will find some way to steer the discussion over to it.

5. the optical layer analysis... see above.

An open 1/4WL stub detours all the associated frequency
energy into the stub and then reflects it back to the source.
Consider the following:

```
XMTR---------feedline-------+----load
|
| 1/4WL
| open
| stub
```

The stub causes complete destructive interference between the
forward voltage and reflected voltage at the mouth of the stub.
Since the net voltage at the mouth of the stub is zero, no
current flows into the load. All the current in the feedline
is flowing in the stub and is reflected at the open end. The
reflected waves head back to the source. Therefore, for lossless
feedlines, all the attenuation/interference occurs in the source.
Of course, for real-world feedlines, I^2*R losses will occur
because of the high SWR at the associated frequency.

The effect of the above stub is much like shorting out the load.
Shorting out the load increases the dissipation in the source.

a new theory! now i'll have to add the traffic theory of waves to the list. just who posts this detour sign? so does all the energy go down to the end of the stub and have to make a u-turn to get back? are you sure they aren't issued a ticket for doing that?? and then again at the junction they have to be directed back to the source, sounds like a job for robo-cop! got to be fast to direct all those waves back and forth!

>The stub causes complete destructive interference between the
>forward voltage and reflected voltage at the mouth of the stub.
>Since the net voltage at the mouth of the stub is zero, no
>current flows into the load

oh, oh! i know this one!! but if the voltage at the mouth of the stub is zero, how does any wave flow down into the stub? there is no voltage there to drive it?? how does the incoming wave know to not flow past the stub connection and get reflected instead?? doesn't that make it a virtual short and just reflect back to the source from there?? but wait, how does the stub get hot then?? where does the current at the end of the stub come from?

Plus if BPL does "threaten" to enter a market, the DSL and cable guys will drop their prices to keep from losing market share. So I bet they are monitoring this situation closely. The latter already know it is price that keeps some people from switching from dial-up. Just look at some of the recent ads on TV for their promotions. Cable had been advertising a $29.99 introductory offer and now they are offering a $19.99 introductory offer. DSL and cable know that they have to get close to dial up prices to get the customers.

Not a new theory. I learned that at Texas A&M back in the 50's.
I had a pretty smart RF prof. It's the same thing that happens
without a load.

XMTR---------feedline---------------open

> so does all the energy go down to the end
> of the stub and have to make a u-turn to get back?
Energy is normally completely reflected at a physical open
circuit in a piece of transmission line. Stubs are no exception
to transmission line theory.

> oh, oh! i know this one!! but if the voltage at the mouth of the stub is
> zero, how does any wave flow down into the stub?

If the standing-wave minimum voltage is zero, why is the current
at that exact point at its maximum value. Maybe you should review
"Plumber's Delight" beam construction rules and standing-waves.

> there is no voltage there
> to drive it?? how does the incoming wave know to not flow past the stub
> connection and get reflected instead??

Because reflections only occur at a physical impedance discontinuity.
There is no physical impedance discontinuity until the open is reached.

XMTR---one wavelength feedline---+---1/4WL---open
|
load

Note the load is connected at a "Plumber's Delight" V=0 point.

The voltage 1/4WL from the open end is zero. What do you think the
current is 1/4WL from the open end? What do you think the voltage
is at the open. Sounds like you believe that there is no current
or voltage on the entire length of the above since it is an odd
number of 1/4WL's long.

> doesn't that make it a virtual short
> and just reflect back to the source from there??

Nope, in the above example, there is a virtual short at the XMTR output.
Does that mean to you that there's no voltage or current on the entire
feedline? Virtual impedances don't cause reflections.

On a 50 ohm feedline with an SWR of 2:1, an impedance of 100 ohms
repeats every 1/2WL but it doesn't cause any reflections at the
100 ohm points because there is not a physical impedance discontinuity
there.

3868. Re: Non-radiating Feedlines?

Newsgroup: rec.radio.amateur.antenna

Source record: 93573

No.

A "non-radiating" feedline is one on which there is no net current (i.e., no common mode current). In the case of coax, this translates to zero current on the outside of the shield; for twinlead feedlines, it means that the currents in the two conductors are exactly equal in magnitude and opposite in direction.

Pattern distortion is caused by current being induced in a conductor by an impinging field. That current, in turn, creates a field which adds to the impinging field, resulting in pattern distortion. (This is, in fact, the way a Yagi functions.) If there is current induced in a feedline by the field, it's a radiating conductor (because the current causes radiation which interferes with the impinging field). If there is no current induced in the feedline by the impinging field, it creates no field of its own (i.e., it's non-radiating) and therefore causes no interference.

A transmission line placed symmetrically with respect to a dipole won't have any current induced in it, although current can be conducted via a direct connection. A transmission line asymmetrically placed will have current induced in it and will distort the pattern. The feedline of a ground plane or J-Pole likewise has induced current which distorts the pattern. The amount of common mode current flowing in a transmission line can be reduced by introducing an impedance to the common mode current. It's desirable to do this without disturbing the differential mode transmission line operation. That's the function of a balun. The amount of induced current depends strongly on the orientation and length of the parasitic conductor, and might be large or small in a particular case.

By how much does the length of the short-circuiting bar at the end of the
1/4-wave stub affect its resonant length?

What open-circuit resonant frequency does the stub change to when the short
circuiting bar is removed?

In the '60s I worked on heavy ground radar, which produced peak powers of several megawatts. The waveguides for those antennas were routinely kept slightly pressurized with dry air. In the set I worked on the most, the air was pumped through one of two canisters of silica gel dessicant, while the other was being heated and purged of accumulated moisture. The roles of the two canisters was automatically and periodically reversed to assure a continuing supply of dry air. A small hole at the antenna end of the feedline allowed a little air flow to occur. In some climates at least, the waveguides would internally arc if the dry air supply failed.

A balun can reduce common mode feedline currents due to the power supplied to the line by the transmitter, but if the feedline is immersed in an asymmetric radiated field, how does the balun reduce/remove the resulting, unpredictable differential current on the feedline, and its contribution toward producing the net radiated pattern?

Heh, heh, you're on your own for that discussion. I personally
believe it is possible for reflected energy to wind up decreasing
the power consumption from the DC source that is supplying the finals,
which winds up decreasing the load on the 60 Hz power grid, which
decreases the oil required from the Middle East, which tends to
decrease the possibility of world war, which bodes well for the human
race, but that is another thread for another time.

I suppose he was, but I'm thinking of the all the religious broadcasters who've set up shop on the SW bands in the last 20 years or so. They have demonstrated a measure of political clout in that the old rules against domestic SW broadcasting are now freely ignored. These guys have a significant investment to protect, particularly those guys who buy another 100 kW transmitter every 18 months or so.

We bounce between the Physics of Operation and the Practicalities of Engineering. We have experts on all sides of the issue <grin>. And, typically, engineers and physicists both use English but can't communicate well <grin, again grin>

But your basic question is how does one answer your question: "Shorts can't dissipate power and must reflect, so how does a stub work?"

In practical terms, you have answered your own question! Reflections.

In Physics terms, you have to deal with the wave inside the stub and the [V^2(theta) + I^2(theta)] energy storage as a function of position within the stub and the corresponding sources of loss also a function of V^2 and I^2 inside the stub and finally the reflections that exist within the stub caused by the intentional physical short circuit [or open circuit].

So, are you pursuing Physics or Applications type knowledge?

It simply provides an impedance to the common-mode currents. Whether
that impedance is high enough to be effective depends upon the system
parameters and configuration.

Source record: 93587

The radiated field in which a feedline is immersed produces a common mode, not differential, current on the feedline(*). The balun creates a high impedance to the flow of common mode current. The result is that much less common mode current is induced than would be the case if the balun were absent. AM broadcasters put insulators periodically in tower guy wires. Baluns have the same effect, although they're of course not as perfect as the fully open circuit created by the insulator.

I'd also like to add that the induced current isn't unpredictable, as you stated. It has to follow rules like all other physical phenomena, so it's entirely predictable. I have to qualify this, though, by noting that in many or most amateur installations, the path from the antenna along the outside of the feedline to the rig and from there to the Earth is often not well known. And precise predictions of feedline current can't be made without knowing this path.

This effect is easily observed in models, as well as being experimentally verifiable with a small amount of effort. For example, make a simple wire Yagi with wire elements. Slip a few ferrite cores over one of the elements and see what happens to the pattern. What you've done is to reduce the current in the parasitic element, which is immersed in the field from the driven and other elements, thereby reducing its contribution to the total field. Cutting the element (analogous to the broadcasters' insertion of an insulator) has the same effect, although it'll be even more profound than the high but finite impedance of the cores. Quanitative measurements aren't hard to make, either. You can find details of current measurement devices in Chapter 8 of the ARRL Antenna book and other references. When placed over a coax feedline, or over both conductors of a twinlead feedline, they'll measure the common mode current.

(*) I'm assuming here that we're dealing either with coax, or with twinlead whose wire spacing is small in terms of wavelength and whose spacing from the antenna is large compared to the wire spacing. If you put twinlead in a field such that the field seen by one conductor is significantly different than the field seen by the other, you will get an induced differential, as well as common mode current. This won't happen with coax. Unlike common mode current, an induced differential current will affect the properties of the line as a transmission line (that is, change its apparent Z0 and velocity factor). But this would be an unusual condition in an amateur installation, and I'm not considering it here.

You've hit on a key issue here -- interests will cry out
against "premature regulation" or promise to mitigate if regulation is
already in place. Then, when damage to others has been shown to exist,
they claim they've been led down the garden path by being allowed to
proceed in the first place. Next they complain about the "crushing
burden" it would impose on them and their investors to mitigate
damages as per the original contract. Standard tactis for running
roughshod ofer the rights of others.

If waveguide isn't pressurized with a dry gas and it has any pinholes it will breath outside ambient as temperature cycles. Later the water vapor will condense on the walls of the WG and as it collects it will flow to low spots of the WG. You know the rest of the story. In non-operating systems in freezing climates you'll see expanded (somtimes split) WG from water that froze in the low spots.

Yes, it distorts the pattern, radiating or not.
How much depends upon the situation,
frequencies, spacing, size of feedline.
It is a conductive surface so it will distort pattern.
Side mounted on a tower changes pattern quite a lot
depending upon spacing from the tower, you can tune
the pattern that way. dB Products used to have a good
Catalogue that showed this.
I would not expect much pattern distortion from a feedline
very small, but would from a tower.

Some of the broadcasters are pretty ambitious. WYFR bought several about 20 years ago. Then it was WWCR. WWRB already has five transmitters.

I haven't heard as much of WWRB since Alex Jones moved to WWCR, but I imagine Dave Frantz might have had something to say about BPL. This time last year, he was talking about HAARP causing all those tornadoes and the evils of Satan's World Wide Web.

3889. Re: Non-radiating Feedlines?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-11 22:01:23 UTC
From: Richard Fry <rfry@adams.net>
Message-ID: <2iuodfFrt537U1@uni-berlin.de>
Source record: 93594

As a discussion point, consider 1/2-wave parasitic radiators sometimes positioned within a foot or two of FM broadcast transmit elements, to "shape" their patterns. This is the common technique used in "sidemount" antennas that must meet FCC requirements for directional FM broadcast assignments.

A parasitic itself is suspended mechanically in space by a non-metallic support. It has no direct connection to the transmitter, and no conductive physical path to any part of the antenna, its feedline, mounts, or supporting structure.

Such parasitics >do< affect the net radiation pattern(s) of the array.

Isn't a "non-radiating" feedline with a balun just an arbitrary length of conductor, but now with a metallically conductive path to the driven element(s), as well?

The feedline (and other metallic structures) adjacent to an FM broadcast transmit antenna will affect the radiation patterns of the antenna even though the measured match between the feedline and antenna input is extremely good (even 1:1 SWR) -- in which case the line should have no differential current to produce such an effect. What is the explanation for that, please?

No. A "non-radiating" feedline is one which has no significant amount of common mode current. This can be accomplished by making the feedline a length such that the induced current is minimal; by inserting a balun or baluns; and/or by placing the feedline symmetrically with respect to the antenna. I thought I had explained this -- I don't seem to be communicating well.

> The feedline (and other metallic structures) adjacent to an FM broadcast

> that, please?

We've been down this path before, and you've shown that you won't accept the fact that SWR has nothing to do with whether or not common mode current exists on a feedline, and there's nothing I've been able to do to convince you otherwise. You also either haven't read or won't believe that it's common mode, not differential, current that causes a line to radiate and thereby contribute to the overall pattern. But hopefully other readers have learned from this exchange. Once the basic principles are grasped, these phenomena lose their mystery, and they're no longer "unpredictable", but readily measured, modeled, and understood.

Based on past experience, nothing I say will sway you from the way you've chosen to interpret observed phenomena. And I believe I've done enough explaining so that any other readers, who are open to learning

some fundamentals, can come away with a better understanding. So that's enough for now.

+, when waveguide, and/or coax leaks, even a SMALL amount of water has a profound effect on it's ability to move rf! Remember several instances of water inside waveguide, only say, 1/16 th of inch deep, on top of window (a dam of either mica, or teflon, to act as a vapor barrier), completely absorbeing all signals, both ways at 6 GHz! Modern systems tend to use dry air pumps (andrew, Prodelien), but even telephone cables (copper, with plastic, and paper insulation) are often pressurized. And, as an aside, when moisture has penetrated these, oftentimes, the pitcock on one end (lower, or level) is opened, while nitrogen, or dry air is applied to the other end, and allowed to continusly flow thru it, to dry it out, or at least to keep it going until favorable weather appears, to timely replace it! and, IF you look at waveguide fittings (both rectangular, and round, the first gap (if you will is a 1/4 wave choke, , and there is usually a SECOND ring (both recessed) , that an rubber gasket fits in for an air block. the wave guide that it mates to on the other end has only an opening for the waveguide, itself, forming (when both these ends are properly mated , an airtight, and rf tight connection . and to insure correct fitting of them, the screw holes of one (forget which) are threaded, and the other is NOT (only one way to apply them!) --Jim NN7K

I have a question about a CB antenna but I'd like an opinion from someone who knows more about antenna theory than the average CB'er. I have an old Antenna Specialists M-902 Black Stallion antenna that I am thinking about using. It looks like the one here http://cgi.ebay.com/ws/eBayISAPI.dll?ViewItem&item=3093592178 but I don't know how well you can see it. It's a shunt-fed, base loaded antenna that is about 3 ft. long and mounts on the trunk lip. My question is how does it compare to some of the new antennas like Wilson or K40? Wilson claims to be the best http://www.wilsonantenna.com/w1000.htm but are they really that much better? Thanks for the help.

Just curious, Roy. Have you used EZNEC to model an FM broadcast transmit array, feedlines and adjacent tower -- as in the models in Paper 6 at http://rfry.org ? If so, and your pattern results are appreciably different than those, for those same scenarios -- I'd truly appreciate learning from you the reason(s) you might pose for that. Maybe I'm doing it wrong.

I'll be glad to send you the intermediate results: radiators alone, complete elements with feedlines, complete elements with feedlines and tower.

Roy Lewallen wrote:
>I'd also like to add that the induced current isn't unpredictable, as
>you stated. It has to follow rules like all other physical phenomena,
>so it's entirely predictable.

The key to reducing the unwanted feedline current is that knowledge that "it has to follow rules". We can't change the rules, but we *can* change the antenna/feedline configuration so that the rules will work in our favor.

These are the well-known physical rules about the way that voltages and currents distribute themselves on wires, for example:

* Antenna wires carry standing waves of voltage and current, and also so do feedlines if they carry net (common-mode or surface) RF currents.

* A voltage maximum is located at a current minimum, and vice versa.

* Maxima and minima are a quarter-wavelength apart.

* Current goes to zero at the physical end of a wire; voltage goes to maximum.

Whenever you change the antenna/feedline configuration, the rules will then force the voltage and current to rearrange themselves into a new configuration also. So how can we "play the rules" to reduce unwanted feedline currents?

For the moment, let's talk about coax feedline and unwanted surface currents, because it's easier to insert chokes and also easier to understand the results.

The unwanted surface current on the feedline has two components:
* Conducted current, launched onto the feedline from the hard-wired connection at the feedpoint
* Induced current, caused by the feedline being placed in an EM field.

Wherever you insert a feedline choke along the feedline (by winding the coax into a coil, or using ferrite loading) then you are creating a high impedance which *forces* a current minimum at that point. The rules will then force the current distribution along the feedline to change, so that it meet this new additional requirement.

A choke balun at the feedpoint is the single most effective change you can make, because it almost completely prevents conducted currents from being launched onto the feedline.

That leaves the induced currents to be dealt with. These are typically less of a problem than the conducted current, but are very hard to kill. It's rather like trying to squeeze the air out of a long inflated tube. Squeeze in one place by forcing a current minimum, and a new current maximum will pop up a quarter-wavelength away.

Your feedpoint choke has defined a current minimum at the top of the feedline, but by squeezing there you have created an induced current maximum a quarter-wavelength down the feedline. So place another choke there too, and the rules will make it impossible for ay significant currents to build up between those two chokes. By making the rules work in your favor, you have effectively killed the feedline current between the two chokes.

The current won't quite go to zero, and a current maximum will certainly try to pop up somewhere else, if the rules allow... but it probably won't be as large as before, and you can chase that one down too.

There are many other ways to look at the problem, but I've found this viewpoint of "playing the rules" to be quite a helpful one. I hope it chimes with some other people too.

I agree with Roy that SWR itself is not the *cause* of radiating
feedlines.

However, if the feedline is allowed to carry currents and radiate, it
effectively becomes part of a new and different antenna configuration.
That new configuration will have a different feedpoint impedance, so the
SWR will change.

But the SWR didn't cause the feedline current and radiation; in fact it
was exactly the opposite.

Also, Richard is assuming that unwanted feedline currents will always
change the SWR for the worse. That's often true, but it doesn't have to
be - sometimes the SWR gets worse when the feedline current is choked
off.

What's up Roy? Long time no see!

Ok, well, I'd like to discuss this a bit.

So for most of the dipole based antennas (including Yagis), you
can use 6 turns of 4" diameter coils in the coax, to make an inductive
loop that is supposed to prevent current from moving down the outer
braid (non-radiating).

>

Ok, so I understand how the common-mode-rejection-ratio works with
an audio amplifier that has an XLR cable input: signals in phase
(common
mode) will cancel each other out when they reach the input transformer
(balun). And although the XLR cable is shielded, the two signal wires
are more like a twin-lead transmission line instead of like coaxial
cable.

So i'm not sure how to ask this, but coxial cable is obviously a
much different beast than twin lead, so the concept of common-mode
currents
radiating from the line is a bit strange because the outer braid
completely
encloses the inner radial. But this is weird because coaxial cable is

unbalanced already, while twin-lead (or in the case of the audio XLR, shielded twin lead) is balanced.

This is a discussion here:

Making it more directional would require something to become like a beam.
The only other thing you could do is similar to the effect of a corner
reflector. A big piece of foil curved around, but god knows what the SWR or
radiation pattern would be.
Do you just need to block the signal from going in one direction, like
through a wall/window and into the house etc?
It wouldn't really stop people sniffing or watchign what you're up to as
that particular system is very insecure, even with WEP. Stick to good old
wires!

I was wondering how many people have broadband access, so I googled this up:

"A new, national report by comScore Networks indicates broadband Internet access is ready to overtake dial-up access as the top online subscription service in major metro markets in the United States. "

""In the past several months, we've seen the U.S. online population reach 150 million people, and household broadband penetration cross the 33 percent threshold," said Russ Fradin, executive vice president of comScore Networks. "Now we've recorded another milestone, with broadband accounting for more than half of U.S. major market Internet connections.""

If the story is correct, half of the internet users have broadband access where it's widely available, and a third of the country has it. Roughly 50 million people in the US have broadband access.

http://www.ectnews.com/story/33108.html

The story doesn't mention dropping price as much of a driving force in the expansion of broadband, but I don't see how it can't be considered as the main reason. SBC here runs promotional offers with the first few months of DSL broadband for little more than the cost of dial up. Of course, the price goes up after the promotional period ends.

Anyway, there seems to be a wide interest in broadband, as long as it's offered at an attractive price.

6 turns is probably not enough inductance to do much choking on 160m
or 80m.

If the dipole is non-resonant, 6 turns of coax may have very little
effect on any HF frequency.

Hi Roy, Richard,

Perhaps it is because of the naming convention vs. application.

The term more appropriate to the Topic is RF Choke rather than BalUn
(which performs the choking action by implication, and could easily
fail that implication if the incorrect BalUn design is chosen).
Further, as you have noted in past correspondence Roy, a second Choke
(not BalUn) is often required for these VHF/UHF applications to
completely isolate the line.

Hi OM,

Loop has a loaded meaning here in this group, the appropriate term would be R.F. Choke. What you describe is adequate for many applications but needs to be confirmed in practice.

There are three (3) conductors implicit in any discussion of Transverse vs. Common Mode. They are the two wires and ground (ground being the conductor in the either the sense of a body of available charge, or a literal wire). If you have absolutely no reference to a third source of charge, then there is no issue of Common Mode.

The twin lead model in any real application (be it window line, twin lead, or your AF cables) has some interaction with ubiquitous ground and this gives rise to Common Modality issues. These models are fairly obvious, what follows reveals how you have missed the translation to coax:

> So i'm not sure how to ask this, but coxial cable is obviously a
>much different beast than twin lead, so the concept of common-mode
>currents radiating from the line is a bit strange because the outer braid
>completely encloses the inner radial. But this is weird because coaxial cable is
>unbalanced already, while twin-lead (or in the case of the audio XLR,
>shielded twin lead) is balanced.

The discussions in this group are often on shaky ground (pun intended) by lacking discussion of ground. The discussions in this group are often on that same tremulous substrate when the arguments run to Kirchhoff, and tectonic when Superposition is given its fanfare.

The Kirchhoff/Superposition failures of discussion revolve around the normal observation in the reciprocity of load as source. For the coax model, the two conductors are bound just as tightly as any twin lead or conductor pair. If we were to terminate the coax at a shielded load, then the self shielding property of the coax would obviate any discussion of Common Mode. Aside from leakage (if you choose to use braided shield), it is totally absent. If you replaced the coax with twin lead, Common Mode WOULD become an issue (an inverse of expectations), but I will suspend that to return to the coax issue you ask to resolve.

The coax terminates in real world loads that are not shielded and THIS imbalances the system. A current is imparted to the load, and a voltage is developed across it (Kirchhoff/Ohm). To any other system component, this voltage is a source (Superposition) potential (irrespective of where the "energy" comes from). This source, now translated and extended to the feedpoint, sees the antenna, and it sees the coax shield which has some linkage to ground. That is, the exterior of the coax is NOT the same conductor as the interior of the coax. The interior path is self shielded, the exterior is definitely not. Superposition allows us to discard the interior wire of the coax, and to simply view this coax as a third wire whose path is described by the exterior of the shield.

This load-as-source (Superposition), then sees more than one path to ground: one, through the load as we know it (typically the antenna); and two, the coax shield's exterior path. Both offer paths for current and this current is the Common Mode current - by definition, as they are referenced to the Common (ground).

Where the load is balanced like a dipole (a seriously flawed presumption, but usefully accepted for the purpose of argument); then those current paths are equal, out of phase, cancel, and conform to the Transverse Mode. However, this balanced load has a reference to ground (this is where the flawed presumption arises and reveals how the Common Mode originates). So does the exterior of the coax shield. Some part of the balanced load is out of phase with the coax shield, and with ground completing the circuit (as both elements share this Common) then current flows - Common Mode current.

If you snub the coaxial exterior path (or Choke it); then you will successfully reduce that Common Mode current. Examples of snubbing mechanisms are bountifully described in this group.

Twin lead applications suffer from Common Mode for the same reasons when the "balanced" load is in fact unbalanced (quite simple when the literal, physical load, the antenna, fails to present equal relations to ground). This is seen when you observe a dipole with one leg drawn down at an angle (or up away from ground for that matter). The visual imbalance is as telling as any method to confirm. If one end of a dipole is supported in the clear, and the other end runs flat into a wooded area, there is the obvious visual imbalance that will in some way force Common Mode currents into the pristine twin lead configuration. The failure mechanisms are manifold, so further elaboration is unnecessary.

To stir the controversy, the standard FCC model for an AM service antenna (ground mounted monopole) is possibly the single best, real example of a balanced system. ;-)

What do you mean by optimum?? Do you have an infinite supply of money, or is that one of the constraints? Do you have a license to transmit on some frequencies? How much land area on each end do you have to work with? Do you care how much power you need to use, or do you want to keep it below some level? What other constraints are you operating under that will help you evaluate just what "optimum" means? And what are you trying to communicate? That is, can you work with very low data rates, say one word per hour, or do you want to send television signals or high speed data? (What do you need to communicate, and how long can you afford to wait to do it?)

If you want to be able to reliably communicate at any time and you have enough funds, a satellite based system is likely your best bet. Cell phones, with their built-in antennas and self-adjusting power, should be fine if you are close enough on each end to the required infrastructure. (i.e., let someone else do all the RF work for you if you can.)

If you want a direct earth-based RF link, with no relay stations between, you can do it on either high frequencies or VLF. With VLF, it will take very large antenna structures and high power (many kilowatts), but once you have a working system, it will work pretty much any time. On HF, there will be times when it is impossible to establish a link at any power, and other times when one watt is sufficient. Generally expect to use frequencies between 10MHz and 30MHz, and expect to need a license. (You can be sure that other people will hear your communications.) Because the frequency you'll want to use will change with the condition of the ionosphere (which depends in turn on things such as solar activity and time of day and season), you'll want an antenna system that can accomodate a range of frequencies. It probably would be helpful to have some directionality in the antenna, as you'd get with a Yagi or log-periodic array, but a simple dipole antenna will work under the right ionospheric conditions.

You can learn a lot about this sort of thing if you read some amateur radio publications. I suppose current editions of "The Radio Amateur's Handbook" from ARRL would be a good place to start.

Cheers,
Tom

You can purchase or get for free antenna model files.

Should whoever creates these files be making them write protected? I've got ones that I purchased and ones that I got for frree and non are write protected, I would have thought that would be the thing to do. I am presuming that write protection is a parameter than is part of the file, or maybe not, perhaps it's a setting of your PC system. Anyone know? TIA.

As Bill noted, it's telco. Looks like something we used to make, or
at least supported at the end of its life. I suppose a 3-decade
frequency range isn't extreme, but I'll bet it's more (for the
achieved performance level) than most hams get in homebrew directional
couplers. ;-) It's possible I could find more info on it if you're
seriously interested.

Cheers,
Tom

Dear Mr. Bruhns:
Yours was a well presented description of the issues attendant to
terrestrial radio communication.
However, Nibiru is a mythological planet that no radio signal can
reach because it is hidden from view.

I am working on a project to build a switchable impendence balun network to go between my 450 ohm twin lead and auto antenna tuner, using a Palomar rx noise bridge.
I am somewhat confused interpretating the noise bridge readings, and the Palomars book is a bit vague on interpretating the resistance vs the xl and xc readings.
I guess I should take the readings and plug them into a smith chart..but I know even less how to interpolate that little beastie.
any help?

The frequency range, the empedance and the plug, all point to use with
"L" carrier
analog multiplex. The 124 Ohm would be a balanced line and consist of a
shielded pair.
I don't know if 124 Ohm single conductor shielded cable was used

My research and field trials demonstrated that
using a space orbiting array powered by fusion generators
can produce a temporal distortial.

Once the distortion has opened up, use of a tunneling neutrino
partial beam would be sufficient to transmit the information.

Now to receive it on the other end is another story.

What's up Cecil?

ok, you may be right about HF, but for VHF (30-300 MHz), 6 turns
in the coax is enough.

So have you made an inductive coil in coax for HF? If so, how
many turns did you need, and what was the diameter of the turns?

I may need to do this for an AM station one day, but maybe not
because most AM antennas are some sort of end-fed random length
wire with a tuner, where the wire length is greater than 1/4 wavelength.
In other words, i haven't seen any dipole antennas for broadcast band
AM....it would be too long!

Slick

Is that the same as Sitchin's 12th planet? If so, it is
presently supposed to be far, far outside the orbit of
Pluto about halfway through a 3600 year orbit.

I once made one out of a 2-liter pop bottle about 1/3 full
of turns of RG-8X. It worked pretty well on 40m, my favorite
band, but a thunderstorm destroyed it. I have no idea what
the choking impedance was.

If you got them off a cd then it is probably just a setting of the computer. Find the file on the hard drive or move it to the hard drive. using something like Windows Explorer. Then see if it is set as read only. If so uncheck that block.

It took 27 turn here to get decent choking on 80m. But it finally
worked 6" diamater selenoid wound.

Hi Hank,

Simple enough to find out. Disconnect the output of your transmitter.
Set the drive level of your transmitter for full power. Defeat the
ALC. Key down. By the clock or watch, take notes at 1 minute
intervals for, say, 10 minutes. Prepare notes into report. Submit
report here. Total time to perform: 30 seconds - 30 minutes depending
mostly on access to the ALC defeat.

This answers all equivocations about does/doesn't; will/won't;
might/mightn't; could/couldn't; or can/can't. Think about it, you
have probably spent more time than that writing to and reading from
this thread to no certain conclusion.

The following is from the ARRL (main page www.arrl.org to get link) Web site. It would appear that the ARRL is promulgating the view that "History is being made". ARRL stands for: American Radio Relay League.' Relay' is an archaic term kept from the organization's founding days; this is not a wireless mesh network organization, for example.

Mr. Robert Vincent is a Technical Coordinator for the ARRL.

To any non-hams, I would like to point out that the ARRL is an organization comprising a minority of licensed radio amateurs in the US, and that many other highly technical radio amateurs, professional in their respective communities, do not necessarily agree with recent views so posed by that organization regarding UWB (ultrawideband); BPL (broadband over power lines) ; and the press-promulgated claims of the DLM antenna.

Many antenna professional are members of the ARRL, while many are not.

In my opinion, it is fitting and proper to give a voice and forum to this research effort, but ill-advised to posit it as "revolutionary" (URI press release) and "history being made"(ARRL web site) until after the findings have been presented and assessed. It is, in my opinion, more prudent for such an organization to present a neutral face in the absence of publicly available information.

73,
Chip N1IR

"In April, I reported that our Technical Coordinator, K1DFT had been recognized by the University of RI for having invented the most outstanding intellectual property of 2003. Recently, news articles in the New York Times, EE Times and Providence Journal have recognized Rob personally and his invention in very positive reports. His invention is called a Distributed Loaded Monopole and is in process of being patented. Independent validation of Rob's hard work is being performed and he will present a mini-seminar of the exciting new antenna concept at the NE Division Convention in Boxboro, August 14-15. It will certainly be a standing room only crowd in the Cotillion Room. Don't miss it. You'll be witnessing history being made. "

Good engineering CAN solve the world's problems!!!

Just use enough 1/4 wavelength stubs and we can totally eliminate the #1 or #2 cause of international tension!!

Now, the Oil exporting states will face economic ruin! We will have to give them foreign aid!! Damn ... taxes will have to go up!! That means we have to elect a Demo Krapp as president.

Cecil, I didn't know you were campaigning for what's his name!!

I better be careful or my tongue may slip out of my cheek.

In addition to the responses already posted, there is at least one other possible, I repeat possible, requirement for pressurized waveguides, antenna feedpoints, etc. It is to increase the breakdown voltage of the local 'atmosphere' at very high power [e.g. megawatts at microwave frequencies.]

Source record: 93493

Bigger is better! [up to a limit of 102 inches for CB [27 MHz] use.]

A 62 inch antenna is about 54 degrees long. 90 degrees long is a full
size 102 inch whip. A 40 inch antenna is 35 degrees long.

Conclusion: a 90 inch whip is typically 'the best' for mobile, a 54 inch
antenna would be not as good as the 102 but better than the 40 inch
antenna. The 'short' antennas use a small coil to work properly. The
location of the coil contributes to how well the antenna works. But the
102 inch is still better than any shortened antenna.

3941. Phased array antenna patterns

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-12 23:43:35 UTC
From: achilles03@hotmail.com
Message-ID: <fef44ceb.0406121543.2cb48211@posting.google.com>
Source record: 93496

I had a simple question in regards to phased array antenna patterns.
If a phased array is trying to send a narrow beam in a specific
direction, how do the other side lobes get reduced and/or eliminated?
Are the individual antenna transmitters/elements not omnidirectional
themselves? If not, what are the characteristics of their patterns?

I ask this because I'm trying to understand how tracking radars can
send narrow beams in the desired direction without significant
secondary lobes to interfere with returns from the desired lobe.

Thanks in advance for any insight!
Dave

Dave,

Actually phased arrays have existed in commercial broadcasting AM (day/night
patterns) as well as some FM.

The best way for you to visualize a phased array is to have 2, 3 or 4 stones
hit the water at the same time ....
you will see patterns emerge as cancellations happen.

This is not an imperative of design;
>If not, what are the characteristics of their patterns?
They add or subtract according to phase offered;
>how tracking radars can
>send narrow beams in the desired direction without significant
>secondary lobes to interfere with returns from the desired lobe.
How indeed, they are not immune from these issues.

Phase and distance are co-equivalent when you speak of multiple
sources. When one source excites resonant elements, those element's
create a phase lag/lead and combine with the original signal with a
phase lag/lead that is correlatable to physical separation from the
exciting source. The designer conspires to arrange all such
times/distances/lags/leads/phases to combine additively/subtractively
to create the desired pattern. Simple patterns like the figure 8 of
the dipole involve few components, but also reveal broad
characteristics for the same reason.

If you want a sharp beam with small fringing lobes, you have to invest
in quite a few times/distances/lags/leads/phases elements. Complexity
does not bring order easily. However money might. Those who build
radars are used to just such a lubricant. The dishes you see offer a
continuum of times/distances/lags/leads/phases with the added benefit
of fairly good shielding from a lot of their sources of grief.
However, they are constrained by physical necessity of being pointed
towards the area of interest.

Other radar designers using phased array sources, use massive
parallelism. Look at a picture of the USS Enterprise. Nearly the
entire surface area of the Island is radiating elements on all four
sides. Each and every source offers a very simple characteristic with
a variable delay line between it an free space - and of course, there
is some distance involved between each element and the next. Given
that those delay lines are addressable and individually setable, beam
steering is obtained through a rather simple concept.

If I recall my former trade correctly, some of the sources in the array can be employed separate to the main combination - sort of like picture-in-picture technology. :-)

Nige

Have you already looked at sites like this??

http://www.techtastic.ca/articles/homemade-antenna.html

There are so many ways to get directivity at 2.4 GHz that I wouldnt know
where to start, unless I knew more about your constraints. I might be able
to be of some help with this project since I am currently involved with
providing a friend with Broadband coverage on his boat via WiFi.. But, I
am no expert. I havent designed antennas since 1970 and have almost never
thought about antennas since them.
And, there are some really knowledgable antenna designers here on this
news group.

3952. Re: Shorted 1/4 wave stub ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-13 03:22:19 UTC
From: Al <aldhearn@bellsouth.net>
Message-ID: <6BPyc.150$lr2.64@bignews2.bellsouth.net>
Source record: 93507

Sometimes, it's useful to think about problems such as this in terms of analogous systems that behave in similar ways.

For example, imagine a gasoline-powered engine driving a water pump though a friction belt and pulley. The pump is attempting to pump water into a short plugged pipe (shorted transmission line). After the first couple of seconds the reflected water from the plugged end creates a back pressure on the pump, a situation in which the pump is then not capable of delivering additional water to that which is stored in the pipe. Now, a number of things can occur, short of mechanical failure of some part of the system:

1) the belt between the motor and pump can start to slip, dissipating the energy generated by the motor as heat lost to friction in the belt and pulley

2) the motor can slow or cease to function, incapable of working against the increased torque (impedance) created by the belt that has been constrained by the pump that can't pump water into the plugged pipe.

In case 1), the power is being generated by the motor, but it is not being delivered to the load. It is being dissipated (converted to heat) `in between.
In case 2), the power simply cannot be created. The motor can't work against such a load. The power is not being dissipated anywhere -- it's simply not being generated. As Cecil has suggested, in this case, the engine stops, which stops using gasoline, which reduces the demand on the Middle East oil supply, which lowers prices, which .....

Case 2) is not one in which reflections "cancel" the energy being generated, although it can be thought of that way. Energy can't be "canceled" (a fundamental law). If a generator isn't delivering energy to a load, it's because the energy either doesn't exist (isn't being generated), or it's being rerouted, stored, or being converted to another form.

Although this analogy could be complicated by making it a pumping system that generates sinusoidal water pressure waves with wavelength-related pipe lengths, it doesn't need to be for it to work.

==========

To understand how things work it is necessary to be familiar with elementary trigonometry. Its quite simple really.

Without trigonometry you just have to accept that's the way things are.

Geordi didn't have the right script writers. Any decent writer
would have had him take a hair-pin and modify the food replicator
to create the necessary neutrino beam. Of course, the replicator
would have had to be set to "ice_cream.ben_and_jerrys" to get it
all together.

There's really nothing special about a phased-array antenna.
It is a radiating aperture, just like the mouth of a horn
or the front of a parabolic "dish". The only difference
is that the phase and amplitude of the excitation across
the aperture can be much more finely adjusted to "squint"
the beam.

But the essential tradeoff remains: the larger the aperture,
the narrower the beam. And, like horns and reflectors, one
can reduce the sidelobes by not exciting the outside elements
as strongly, but with a corresponding reduction in gain from
the maximum obtainable for a given aperture size. This is
called illumination tapering and is done on all antennas
in one form or another to work the gain/sidelobe tradeoff.

>I ask this because I'm trying to understand how tracking radars can
>send narrow beams in the desired direction without significant
>secondary lobes to interfere with returns from the desired lobe.

Most radars go for wider beams with lower sidelobes because
the overall system performance is better. But the sidelobes
are only reduced, not eliminated entirely.

Oh, yeah, and about the patterns of the individual elements,
they have to be as non-directional as possible. The deal is
that the overall antenna pattern is the result of the PRODUCT
of the array factor with the pattern of the individual elements.
If the individual elements have reduced gain off boresight, the
entire antenna gain is reduced off-boresight as well, limiting
the angles at which the beam may be "squinted".

I can trust mnyself, but if the original files were write protected when the
came when downloaded, then it would be a safety measure from accidentally
altering the original files. I'm going to mess with the originals but save
the altered input files under a slightly different file name. I think I'm
making a perfectly valid point.

Phased arrays are fun to play around with (on the 2-meter band especially)
You can experiment using physically manageable components.
You can switch elements phasing by using different lengths of feedline
its interesting - a good hobby in a hobby

You could just change the file attribute of whatever you want to protect to "Read Only," after you copy it off your CD or wherever. That will prevent overwriting the original file with a corrupted version.

Find the file(s) using WIN Explorer, right click on the filename(s), then mark as read only.

Gurus,

My brother who is working for an NGO is east africa wants me to buy him an HF ham radio where he can communicate with his colleagues in other parts of the world. His colleagues use CODAN, but he can't afford that brand.

A local dealer is recommending that I buy FT-857 with ATAS-120.

Here are my questions?

1- Is this combination a good fit and how reliable is it?
2- Can he communicate with other radios as far away as 3000 miles?
3- Do I need a duplexer if he is using just the HF band?
4- The radio will be mounted on a land cruiser? Where you recommend the antena mounted on?

Many many thanks for your help.

If you want write protected files, Make a CD of all the files you want
write protected, then copy them back to your hard drive.

Even if you do accidentally change thefiles, you have an original
"write protected" file to go back to.

Perhaps you are not experienced with computers. (no sin, that) It
really isn't a big deal though, to not have write protected files when
the originals are so accessible. And even then, working with a renamed
file instead of the original is along the same line of reasoning as
backing up your files. You DO back up your files, don't you?

Finally, if the files came in write protected, there would be plenty of
people that would complain about that!

Hi Dave,

Sorry, but that was too terse.

I wasn't in D.C. but for a short event. It was not long enough to
sample the full gustatorial offerings of the region - if that was the
implication. Also managed to run across a bottle of my favorite Rhum
St. James. (Should'a brought a bottle of that back to read this
thread through its bottom.)

You mess but you do not alter the original.

When editing nec input files you have got to be careful not to save because
then the original file is not original anymore.

I thought it might be better to download files that come write protected
from the start.

Hi,

I use an FT857 & the ATAS120 on my vehicle and it works fine, but the antenna does need a good ground, mine is mounted on the roof. I also put an extra ground wire from the vehicle chassis to the radio and it works fine from 40M upto 70cms using a Diamond MX62M di-plexer. The antenna also prefers to be mounted high on a vehicle rather than on the side where it has the body of the vehicle next to it. As for contacting stations 3000 miles away that will depend on freq and propagation, although I have worked US stations on 17M from the UK when mobile.

Hope this helps.

Check the physical size of the FT-857 and see if your friend has the
room for it.

Smaller radios with similar specifications are the FT-100D, and the ICOM
706 MK IIg. All of these units, 857, 100D and 706, run 100 watts and can
easily cover your 3000 mile range [with decent antennas] on the various
ham bands between 20 meters and 10 meters depending on atmospheric
conditions. I routinely cover 3000 mile range from my truck using a 100
watt radio, an antenna tuner, and a reasonable whip antenna.

My only question has to be with the size of the radio, not it's
performance. If you friend has the room for the 857 go for it! If not,
the FT-100D or the 706 should meet his/her needs.

Well perhaps I should reword my comment. It seems like many responders are getting into the politics of reflections, some into the theory but I believe it's a science and should be explainable. Theories are used to explain what goes on inside a black box that we can't open, just an input and output. But a shorted 1/4 wave stub is about as far as you can get from a black box.. I'm curious!
There are no stupid questions, just stupid people asking and that's me.

Hi Dave,

I offered a very simple test. There is the path of an objective
result, or the path of a subjective and ponderous appeal.

You do have a rig, do you not? You could perform the several steps to
come to a conclusion I presume - otherwise disabuse me of this talent
I inferred in your behalf and state which political party you are
affiliated with.

Use a TDR. Observe TV ghosting. The reflection model is perfectly
valid and consistent and the outcomes using the reflection model
are the same as any other valid consistent model. An S-parameter
analysis uses reflection/transmission coefficients, i.e. the wave
reflection model. If an S-parameter analysis is not valid, a whole
@#$%-load of electronics should not be functioning as they do.

I'm not entirely certain, but I believe the H-parameter analysis,
the Y-parameter analysis, and the Z-parameter analysis all use
the reflection model and are valid for impedance discontinuities
in transmission lines.

Hi Hank,

Seems like several many have offered the simple mechanics to satisfy
the question.

Would you like to comment why they did not? If you find the
reflection based argument tedious (and it can be that in spades); then
perhaps you should offer an outline of the terms to be employed or the
constraints of the stub's application to reduce shot-gun answers that
bloat the thread.

The solid-state political creed seeks to discredit reflections by using
only the solid-state shortcut physics. These shortcuts certainly work,
but they do not dictate reality. Man, not Mother Nature, takes those
shortcuts. Witness the inability of anyone to present an example of
the existence of standing-waves in a single source, single feedline,
single mismatched load system, without the existence of a forward-
traveling wave and a rearward-traveling (reflected) wave.

The same solid-state political creed dictates the definition of source
power. It says that if reflected power is taken in the source, then
it was never generated in the first place. Never mind that energy can
be proven to have made a round-trip to the load and back to the source.

Premier RD-98 is a good one. It's the very thin and flexible type which comes in handy as it's 17" long, and has an SMA connector which is what the VX-2 uses. If you don't want something that long they also make the RD-9 which is only 7" long. I have both, have found the RD-9 to be on par with the stock antenna (Yaesu, FT-50 which I believe uses the same antenna as your VX-2) though the flexibility is a nice feature; the RD-98 is head and shoulders above the stock antenna.

Richard, I'm a retired EE and have used stubs extensively in USAF Missile systems C-band and S-band design. They work, they get warm, they increase the insertion loss in the transmission line system, they work, they work, ...

We use the word 'THEORY' too loosely in ham discussions. Theory is the state of experimental verification between Hypothesis and Law. Many times we use the word 'Theory' when we should say that Physics/Mathematics explain the observation as follows: etc.

In a shorted 1/4 wavelength transmission line 'stub' we have a current maximum at the physical short circuit. We have a high impedance 1/4 wavelength from the physical short circuit. The voltage and current have a sinusoidal relationship along the length of the 'stub'. There is a forward and reflected wave within the 'stub'.

There are several loss components within the 'stub' including I^2*R and V^2/Rl [Capacitive dielectric losses] and 1/2L*I^2 [Leakage Inductance losses]. Therefore the presence of a stub increase the insertion loss in the transmission line sub-system; conversely, the removal of the stub reduces the insertion loss in the transmission line sub-system.

In EM Physics, circa 1958-59, the equations of state for the stub included both a transient response and a steady state response. I have not solved these equations in more than 20 years [I probably forgot how to solve them in any event!]

With all this said and done I find it interesting to follow the discussions and learn many things, some of which are correct <grin>.

Perhaps I might be of assistance by providing some orders of magnitude.

A 1/2-wave stub line, 1 metre (39.37 inches) long constructed of a pair of polished copper tubes, each 1/2-inch in diameter, centers spaced 3 inches apart, at 150 MHz (not very far from 2 meters) has the following characteristics -

Zo = 299.8 ohms.
Attenuation = 0.0024 dB.
As a tuned circuit, Resonant Q = 5800.

When short-circuited -
Parallel input components of Zin -
Rsc = 0.08 ohms,
Xsc = -j*582 ohms.

When open circuited -
Series input components of Zin -
Roc = 1.11 megohms,
Xoc = j*38.6 ohms.

These and many other interesting values can be very accurately and rapidly calculated, from 20 Hz to 1 GHz, by using program RJELINE2 available, free issue, from website below.

Contributors to this newsgroup, who by no means are lacking in intelligence, may then be able to get their feet on the ground.

From: Richard <nearlynews_email@ntlworld.com>
Message-ID: <2j59mlFthfrlU1@uni-berlin.de>
Source record: 93453

I'm getting an initial impression that there might be three basic forms of traditional yagi (not log-periodic) when considering the issue of bandwidth.

Common Yagi (whatever that may be) . This has a fairly narrow bandwidth, not sure of the typical bandwidth in precentage terms of the designed frequency. Perhaps 1% at a guess. Here there has been no effort to concentrate on making any form of wideband antenna.

Optimised Wideband Antenna (OWA). This has a fairly wide bandwidth, not sure of the typical bandwith maybe 3 or 4 percent of the design frequency. Here some effort has been put into making something of a wideband antenna, but the design is not as wideband as is possible.

Wideband Yagi. This is typically the antenna having the widest bandwith. Not sure of the typical bandwidth, but perhaps about 7% of the design frequency.

If you were to draw up a list of traditional yagi' designs (including call letters of the designer if there is one) and place them in order of increasing bandwidth, what kind of list would you get?

Here is my measly effort:

Yagi (under no classification but yagi)
OWA
Wideband Yagi.

I'm not sure where in a list you put DL6WU, W4RNL, DJ9BV, + other designs I know not of. Does a DL6WU yagi come under OWA or wideband yagi? Has anyone drawn up a definitive classification?

> Has anyone drawn up a definitive classification?

Further:

Is there in existence or has anyone ever thought or is there any possible usefulness in a rating system for yagi antennas? You ascribe a value to each of the main the characteristics and you publish the rating along with the design.

Something like:

Gain range (dB): 0-2 2-4 4-6.....infinite
Rating: 1 2 3 10

F/B range (dB): 0-5 5-7 7-10....infinite
Rating: 1 2 3 10

Bandwith range %: 0-0.5 0.5-1 1-2 2-4.....infinite
Rating 10

Then you would publish in the article for design something like:

G8VOQ "Super-duper-all-singing-and-dancing yagi":

Parameter Rating
Gain: 10
F/B: 10
Bandwidth: 10

What, AGAIN? Spare us Chipster, you're into some more of your online
gamesmanship and you're obviously twisting your just as obvious
dislike of the ARRL into unmitigated BS. The guy who wrote the piece
you've cited is *NOT* the "voice of the ARRL", the ARRL as an
representative organization is not involved in any of this nonsense,
not even close.

http://www.arrl.org/sections/index.html?sect=RI&monthly=1

He's just one of eighty-something volunteer ARRL "Section
Communications Managers" who are scatterd all over the country and
that's all he is. SCMs are *not* ARRL HQ technical staff or ARRL
policy generators. As this link illustrates SCMs compose and post
unedited chatty reports on activities within their ARRL sections. End
of. You've copy-pasted one paragraph of one of this guy's personal
comments on the K1DFT thing into something it's not in order to suit
your own personal agenda(s).

Not that any of this is new information for you eh Chipper?

>each of the main the characteristics and you publish the rating along with
>the design.

Virtually all the latest Yagi-Uda work is aided by simulation and computer optimization. This is assessed through a 'cost function' (also known as figure of merit; objective function) which is a mathematical formula that weights bandwidth; gain; feed impedance; F/B and so on.

There is no 'one' cost function, and tailoring it requires some finesse. The tradeoff usually occurs in bandwidth compared to gain and F/B. The bigger the value of the cost function, the better the candidate design.

A simple expression that could be used is

CF= aG +bF +cW (1)

where G is gain in db; F is F/B in dB; and W is bandwidth in percent. the a,b,c coefficients thus determine which is a bit more important to you, as well as allowing relative normalization.

Hi Brian,

Nice to hear from you.

The ARRL NE Convention at Boxboro is planning a two hour forum for Rob Vincent's work. Perhaps you might present an example where a 'new' technical subject has been given that much focus at an ARRL sponsored event?

I am of the opinion that it is proper and fitting to have this venue as a forum for Rob's work, but the time devoted would appear to indicate some sort of point of view, don't you think? Is there, for example, a separate talk by W8JI telling us why the Vincent claims are not accurate? Balance would be very nice. That is my opinion; yours may differ.

Also, your point is well taken. It would thus appear that perhaps--if there IS such a strong interest from the members--that the ARRL do a short, factual, and newsy piece on their web site. Otherwise, in an ARRL sponsored event, and an ARRL sponsored web page, there is certainly a point of view so cast, don't you think, Brian?

I do have a personal point of view, Brian, that is frankly, quite well informed and objective. It is not an agenda. I am not an activist.The ARRL has done many good things, and it has done others that some feel are more activist oriented, and--in my opinion-- not fostering new technologies such as UWB; cognitive radio; and of course, BPL. Hams, in recent years, have little (if any) to show in being part of the technological revolution in wireless that has occured in the last decade. It would be a shame if the DLM designs of Vincent were used (as a counterexample) in that context for PR sake by the ARRL or anyone else--if, and until, the claims are verified and the technology has been demonstrated to offer NEW and UNIQUE benefits.

I speculate that we will see a full, front page article on the wonders of the DLM antenna in the QST September issue, to coincide with the Boxboro ARRL Convention. Of course, that COULD be construed as an ARRL 'agenda', Brian. And, of course, my opinions may prove to be only partially justified here, and maybe totally wrong. Who knows:-)?

Brian, do you have a technical opinion on the claims of the Vincent DLM technology? I appreciate that you may wish to wait for more data.

I was thinking that for every published or generic design maybe there could
be a kind of master list that you could consult.

ie like:
Rating
Antenna Gain F/B Bandwidth

OWA (5 ele) 3 3 5

Standard Yagi (5 ele) 4 3 2

DL6WU (10 ele) 5 6 2

DL6WU (15 ele) 6 6 2

But, you could just use the actual values I suppose. You would have in this case three seperate tables, this one above if low to high on the gain parameter.

I am not aware of such a list. It would certainly be useful.

Typically, a designer has a specific need and the optimization solves for that.

Being an engineer, I am quite familiar with trigonometry. I believe
you didn't fully understand my question: How do the other side lobes
get reduced and/or eliminated? Theoretically, in some phased array
antenna configurations, some lobes have an undesirably high a gain. I
was wondering what filters / engineering work arounds were used to
mitigate this. Other posts have adequately answered this question,
however. Thanks anyway.

Yes, you can use 5 ohm tv coax but you will be better off using 50 ohm rg 8 or rg 58 cable as the output circuit of your radio is optimized for the 50 ohm cable. There is aloss of power in the mismatched cable. Not much but it is there.
If you must use 75 ohm cable then investigate using a matching section of 50 ohm cable.

Those are all examples of two port parameters, good for your basic linear, time invariant system. (While you're at it, don't forget the transmission parameters, Cecil.) They'll work with any old lumped or distributed system as long as it's linear, has two ports, and is time invariant.

You can't really use S-parameters to prove reflections exist because S-parameter theory assumes reflections exist even when they don't, as in the case of
transistor characterization - much like calculating the VSWR in a zero length transmission line. They're good for analysis, though, as long as you don't get carried away and look on them as proving something about God, the Universe and Everything.

Electrically, the tv coax should work nearly as well as rg58.

Only problem I see is the foil inner shield in tv coax might be
trickier to solder to a standard pl-259 plug that you will screw onto
your transceiver. The connectors they used to attach to a tv input
won't fit your transceiver.

In tunnels leaky feeders are used. They leak just enough signal to be picked
up at a close range.
You could try using very bad coax :-)

4015. RF transmission through various materials

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-14 16:06:12 UTC
From: achilles03@hotmail.com
Message-ID: <fef44ceb.0406140806.5752ca8@posting.google.com>
Source record: 93469

I was wondering what the general relationship between frequency and its ability to transmit through various materials? For instance, 1GHz and 1MHz obviously transmit differently through materials. I'm curious as to what material properties are involved (i.e. dielectric constant, density, etc?)

The main reason for this questions is I'm wondering how well 1+ GHz (GPS) signals transmit through about 1.5 inches of expanded polystyrene (styrofoam).

Thanks in advance for any insight!
Dave

Hi Dave,

Such material at that frequency is often used to construct a di-electric lens. That is, when the di-electric constant (which is analogous to index of refraction) is taken into account of curvature which, in turn, is of sufficient size with respect to wavelength; then you have the means to construct lens of the common shape you encounter for light lenses. This means both follow the same characteristics given the same shape. For a slab of Polystyrene, it would be equivalent to plate glass (no gain/magnification).

As long as your di-electric is free of impurities, then for all intents and purposes it is as clear to RF as glass is to light. Add impurities and you stand the chance of making sunglasses for your antenna (unfortunately the analog of sunlight would be your precious RF).

Optical lenses are hundreds to thousands to millions of wavelengths across. On the other hand, RF lenses stand to be much smaller in relation, and as such there is a minimum size whereby no advantage may be found (don't expect to build an effective, but sloppy quarterwave lens).

David

I'd submit that your question is very difficult to explain within the
consraints of a newsgroup paragraph or two in a news group. The subject of
aperature distribution has been studdied for years and years by thousands
of high level engineers.
Although it is desired to minimize the sidelobe level from scanning flat
phased arrays, there is a limit to how low the sidelobes can be made. They
sure dont go to zero.
A side looking scanning antenna of phased elements will have individual
elements who's pattern is appropriate for whatever area is being scanned.
The pattern from each element wont be omnidirectional.

It might be a good exorcize for you to draw a plot on a piece of paper with 10 antennas in a row. You can quickly see that the array will have max gain at some power distribution and have sidelobes that change appreciably when the distribution of power (and phase) is varied over the length of that array.

Off the cuff, I'd say it'll have no noticable effect...
Some of this can have additives which may change the equation.

Lenses...Hmmm. Interesting idea.

I can try it and see what effect I can see on the signal strength bars on
the GPS.

I do know that my older GPS (Sequential receiver) doesn't receive in the
house. I suspect it is from the foil backing on the fiber glass insulation
in the ceiling.

Thanks! You know any simple phased array configurations that are easy to mathmatically model? I've played with a 4-element array all located on the same axis just for fun to see what resulted (and to make sure my equations were right), but I'd like to find some real-world systems (hopefully without too many elements) to play with. Any digrams exist on the net? (dimensional relationship between elements, etc).

Thanks again!
Dave

On the contrary, if one assumes same-cycle reflections, the reflection model works perfectly. Why wouldn't a 50 ohm source looking into a 100 ohm resistor suffer an immediate reflection (energy rejection)? :-)

4025. Re: RF transmission through various materials

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-14 19:10:23 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <10cru14agiclb78@corp.supernews.com>
Source record: 93380

"Ability to transmit" is a bit vague. In any material, a wave will encounter attenuation, an impedance, and a velocity, all of which are determined by material properties of permeability, permittivity, and loss tangent. The change in impedance from free air causes reflections, and the change in velocity causes refraction. If your main concern is attenuation, it'll be negligible for the styrofoam at that frequency. If you're interested in calculating precise values or investigating other materials, a good reference is Kraus's _Electromagnetics_.

Something to keep in mind is that phased arrays with a large number of elements are simpler in one respect than ones with just a few elements. In the first case, you can make the assumption with reasonable accuracy that the feedpoint impedances of all elements are the same, since all are in essentially the same environment with respect to the other elements. For most simple phased arrays, you can't make this assumption. So while pattern analysis of simple phased arrays is easy once you assume equal element currents, actually getting those currents can be more difficult than you might assume. If you're interested only in the patterns and not how you'd actually get the currents you need, simple trig is enough. But that's not enough to enable you to actually design and build one that'll work as planned. Chapter 8 of the _ARRL Antenna Book_ describes what has to be done to make simple arrays work properly, as well as describing a few common simple arrays. There are also a few examples of phased arrays with the free EZNEC demo (http://eznec.com), where you can save yourself the math and immediately see the effect of changing element currents.

Source record: 93384

Transmission loss through materials depends on 2 factors. Loss tangent and dielectric constant. Loss tangent is often the lesser of the problems, but is simple exchange of the wave energy for heat caused by several possible mechanisms. Look up the operating principles of microwave ovens. Dielectric constant manifests itself as an impedance mismatch at each surface, which causes reflections. At a specific frequency, this characteristic can be used to make the material transparent, as in ceramic radomes for spacecraft.

In your case, the loss tangent of polystyrene for RF is among the best if there is no moisture trapped in the foam (closed cell type preferably), and since the dielectric constant approaches that of air, then the loss at the GPS frequency will be virtually nil.

Hello All

I am trying to ID The MFG of this mast Please Visit
www.fastpcsolutions.net/id93.htm for pictures of this mast. My intention is
to erect the mast and provide for free wireless internet service for free to
The students of my count whom the board of education gave each student an
apple I book with wireless network cards in them of course i wont be able to
service the whole county but i will be able to give this service with the
right antenna to students within a 1-5 mile range.
I need to know who the MFG of this mast is so i can get structural
information about it. The inspectors department needs this information to
approve it place ment like: How much wind it will withstand and the maximum
pad depth and with i will need.

All help is greatly appreciated and if there is any engeneers that can help
me with this in getting it approvet i would appreciate it also

if there are no components that introduce a time delay it would. so no
transmission lines allowed... hence no reflections. and you are back to a
simple lumped resistor problem.
```

Say a beam has 5db forward gain and a front to back difference of 20db. Where does the extra 15db go? I mean, if you loose 20db off the back on transmit, I assume you also loose that much on receive. What happened to the 20db? Did it burn up as heat? What am I missing here?

The analogy to a balloon is pretty apt.

Squeeze and pinch the back so only about 1/50 th of the air that used to be there is left. The rest gets distributed towards the front, and makes the front side more than a factor of two bigger. But the ratio of the amount of air in the front to that of the back is very big--say, 100.

That's a 20dB F/B.

Hope that helps.

Dave

How much of *what you want to know* could be learned from a test in the
microwave??

As you probably know, it will be very difficult to include enough
Polystyrene around a GPS receiver (and its antenna) to effect the accuracy
of its readings.
I get pretty good accuracy from my DeLorme GPS while it is inside my
house. That is actually a statement about the poor construction of the
house, I suppose.

Jerry

4040. NASA 'EVOLUTIONARY' SOFTWARE AUTOMATICALLY DESIGNS ANTENNA

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-15 00:08:43 UTC
From: fractenna@aol.com
Message-ID: <20040614200843.16591.00001069@mb-m15.aol.com>
Source record: 93396

From NASA Ames Press release:

"NASA artificial intelligence (AI) software - working on a network of personal computers - has designed a satellite antenna scheduled to orbit Earth in 2005.

The antenna, able to fit into a one-inch space (2.5 by 2.5 centimeters), can receive commands and send data to Earth from the Space Technology 5 (ST5) satellites. The three satellites - each no bigger than an average TV set - will help scientists study magnetic fields in Earth's magnetosphere. NASA scientists have spent two years developing the evolutionary AI software that designed the antenna.

"The AI software examined millions of potential antenna designs before settling on a final one," said project lead Jason Lohn, a scientist at NASA's Ames Research Center, located in California's Silicon Valley. "Through a process patterned after Darwin's 'survival of the fittest,' the strongest designs survive and the less capable do not."

The software started with random antenna designs and through the evolutionary process, refined them. The computer system took about 10 hours to complete the initial antenna design process. "We told the computer program what performance the antenna should have, and the computer simulated evolution, keeping the best antenna designs that approached what we asked for. Eventually, it zeroed in on something that met the desired specifications for the mission," Lohn said.

"Not only can the software work fast, but it can adapt existing designs quickly to meet changing mission requirements," he said. Following the first design of the ST5 satellite antenna, NASA Ames scientists used the software to 're-invent' the antenna design in less than a month to meet new specifications - a very quick turn-around in the space hardware redesign process.

Scientists also can use the evolutionary AI software to invent and create new structures, computer chips and even machines, according to Lohn. "We are now using the software to design tiny microscopic machines, including gyroscopes, for spaceflight navigation," he ventured.

Four NASA Ames computer scientists wrote the AI evolutionary program that operates on 120 personal computers, which work as a team. The scientists wrote the AI software because it can create designs faster than a human being can do so.

"The software also may invent designs that no human designer would ever think of," Lohn asserted. In addition, the software also can plan devices that are smaller, lighter, consume less power, are stronger and more robust among many other things - characteristics that spaceflight requires, according to Lohn.

The Office of Exploration Systems at NASA Headquarters, Washington, is funding development of NASA Evolutionary software. Detailed information is on the Internet at:

http://ic.arc.nasa.gov/projects/esg

Space Technology 5 satellite details are on the Internet at:

Remainder deleted

Three questions emerge from my foggy brain wrt to a current project.

1. What sort of choke loading on a feed line would be most
effective at 70 cm, ferrite or coil wound from coax.

2. Could ferrite loading at a feed point take the place of say a
1/4 wave sleeve balun matching the unbalanced coax feed to a
centre-fed dipole element.

3. What grade of ferrite bead would best be useful at 70cm.

Thanks in advance.

Well, when you can get 18db gain out of a paper clip VHF antenna, you done
good.

Then how come it doesn't give us 20db of forward gain? I mean, we blocked 20db off the back and applied it to the front and we still only have 5db of forward gain. Where did the extra 15db go?
I think those are typical figures for most triband beams I've seen advertised. 5db forward and 20db front to back. I would expect the guy on the other end to hear me by 5db stronger than a dipole and my beam to reject signals by 20db off the back. Well let's say the guy on the back side of my beam hears me at S9 then I rotate the beam around to him. My signal then goes up 20db. Right? Is that 20db of gain? Well in comparison to the other way, yes but in comparison to a dipole, no since the dipole would have been only 5db less than the beam in the favored direction. Now the dipole would be 15 db stronger than the signal off the beam's back end since it has no front to back ratio but it's only 5db down from the beam in the forward direction. Thus we conclude the dipole produces 15db more signal than the beam. Impossible.
Something just doesn't add up.

Evad,

I believe the gain comes from the effective aperture of the back-reflector --which is just a disc. The shaping of the 'paperclip' predominantly is used to affect polarization and bandwidth. It does look like a paperclip. I'm sure it isn't.

In all honesty, this particular problem is not complex and does not require 120 computers to get an answer. I suspect that at least some of the best candidates emerged in just a few minutes of CPU time. It takes about a minute or less to run NEC on each model,with a simple mesh back reflector for the disc.

>Then how come it doesn't give us 20db of forward gain?

It does, if you (incorrectly) define forward gain as being relative to the backside.

As I said, the signal (that) now no longer goes out the back gets its power---redistributed--and that redistribution is like pushing the air forward. It doesn't -- all-- get concentrated in one spot up front, thus the forward gain isn't 20 dB.

Steve- you are compairing apples to onions! Why?? Simply, there is no
absolute relationship between forward gain, in dB, and the front/Back ratio
(also in dB)! The forward GAIN is relative to either a DIPOLE , or an
Isotropic point source! If you were to place a dipole at the same location,
as the beam
(for arguements sake), the signal would be 5 dB louder on the beam, then on
a dipole. And an isotropic
point source (really, an immaginary "antenna", is aprox. 1.8 db dB below a
dipole (beam would be aprox. 6.8 dBi rated) The front to back ratio, on
the other hand, simply means that the signal off the front of the
beam will be 20 dB LOUDER (for want of a better word) than it will be
recieved, if the antenna is turned 180 degrees! Hope this explains it!
that is how any gain antenna works, by takeing power from an
unwanted direction, and concentrateing it in a desired direction! Jim NN7K

Oh, and one thing NOT mentioned, about the Isotropic-- It is defined to radiate equally well in ALL directions-- It has NO Front to Back Ratio (if it ever could exist!) This is why it has a loss in comparison to a dipole , which is directional parallel to it, and has great loss perpendicular to it ! -- Jim

Probably equally effective, although it might be tricky to get a coax coil to resonate at 70 cm, while a ferrite core choke, which is inherently broadband, would be easy.

> 2. Could ferrite loading at a feed point take the place of say a
> 1/4 wave sleeve balun matching the unbalanced coax feed to a
> centre-fed dipole element.

Yes. A properly constructed sleeve balun can be made to have higher impedance, but in the application you describe, a ferrite core choke would be perfectly adequate.

> 3. What grade of ferrite bead would best be useful at 70cm.

I'd probably use type 43. That's a Fair-Rite designation, but ferrites from other vendors with initial permeability of 700-800 or so would work equally well. Cores from that material are readily available in a wide variety of shapes and sizes. Some of the 60 series ferrites would also probably be adequate at that frequency.

I suggest you visit the Fair-Rite website and take a look at the impedances of various cores at the frequency of interest, and choose ones that get you the impedance you need. (Unless you're running a lot of power, you don't need to worry about whether the impedance is resistive or reactive -- just look at its magnitude.) You can place cores on the outside of the coax and get an imedance that's the product of the number of cores and the impedance of one core. Or you can wind the coax in multiple turns on a single core and get N^2 times the single turn impedance, where N is the number of turns. 500 - 1000 ohms or so of impedance is adequate for most applications. If you have an antenna analyzer that operates at that frequency, you can measure it. Otherwise, just go by the manufacturer's stated value of impedance at the frequency of interest.

RF energy travels at the speed of light. For the length of time it
takes for the energy to reach the resistor and reflect back to the
source, the source sees 50 ohms. That length of time is not zero.

My car goes about 100 MPH (I assume) in the forward direction, but only
about 15 MPH in reverse. When I'm in reverse, where did the other 85 MPH go?

The answer to that question is about the same as the answer to yours, so
when you figure out the answer to my car question, you'll have the
answer to your antenna question.

Agree Chip. I suspect it is a feed to a parabolic or spherical to get to
18 dB.
It is the amount of aperature to intercept 18 dBi, and that is bigger in
diameter, or
a long slow wave structure. Yes, the laws of Math and physics apply --only
so much gain with a cubic inch in VHF,-- in spite of any AI approch.
Helix has been around since the 30's- 40's, I have a Quartz loaded helix for
10 GHz used
on spacecraft, bout a cubic inch. But the AI stuff, what a waist of tax
money on this kind of project, what happened to Off the Shelf?.
What bothers me is the spunup hype on AI such as "millions of designs" in a
cubic inch, right.
Anyone involved with AI knows it gets into trouble all the time, must be
patched and we make the rules it follows for evaluations.

Even though the length of time is not zero, it's close enough
so that the theorems of network analysis work (at least
at the lower frequencies). Of course, if you want to do a reflection analysis
on a
couple of resistors, each of which is only a minute fraction of
a wavelength long, well, it's a free country. S-parameters assume
reflections and such, and are very useful to the people who use them,
but, as an intellectual tool, it doesn't matter whether there are any real
reflections or not as long as the answers come out right. They
don't really prove reflections in and of themselves, anyway, since it's hard to

prove something based on the assumption that it's true. (I assume it, therefore

it's true.)

You should look at Linux or Mac so you can regain the use of your
computer. You should own your computer and not vis-versa!

;-)

Here is the webpage in plain ASCII text with a link to the FCC website.
Please, making a comment will only take a few minutes.

/***/

The FCC has extended the comment period for BPL. If you value radio, this
may be the last and only chance to have your voice heard to stop BPL from
destroying your hobby. The FCC has extended the comment period for BPL.

It is VERY simple to file a FCC comment. Click the link below and enter

04-37

in box #1 (proceeding number) and fill in the blanks. The simplest way to
comment is to type your comment into the box on the bottom of the form.
Sample comment below.

http://gullfoss2.fcc.gov/prod/ecfs/upload_v2.cgi

If you see fit, please post this to as many portent groups as possible
because numbers count!

More info at http://www.arrl.org/news/stories/2004/02/12/5/?nc=1

If you can't think of any thing to type or wish to make this as painless
as possible, you can cut-n-paste the comment I typed below.

/*****************************/

In Writing, I wish to persuade the FCC from allowing BPL to be
implemented. The destruction or at the least, deterioration of the
shortwave bands is not only a violation of ITU laws that protect

international broadcasters from interference and jamming, it will be destroying many people's life hobby. Amateur radio will be reduced to users with high-power amplifiers and large antennas. Emergency communications will be hindered to levels directly responsible for the loss of life. Also, this will hinder military HF comms reducing national security

There are many technologies that make BPL unnecessary. BPL will never be able to carry the high bandwidth demands for mass distribution of video much less the up-and-coming HDTV.

Thank You!

Your First problem is that you went to a CB group to ask that kind of question. What were you thinking? You will have to match the antenna to bring the feed down to 50 ohms. With a properly matched antenna you should get the full 4 watt legal limit on 11 meters.

Hi LG,

There is great value in automatic design. I just don't think this is the best one to showcase. Just the tech support for 120 computers in a room is probably far more than it costs to get the design commercially. Commercial vendors have come along much, much further than what is described here; that design could have been delivered at a fraction of the cost.

NASA has taken a great initiative as a fostering agency on evolutionary design, but the uncomfortable issue of :'what's NASA doing in the antenna business?' does come to mind from this example.

Now if they were able to design an optimized spacecraft with this tool, that's a different story. The tool would match the challenge and the importance of the problem.

73,
Chip N1IR

It isn't a miracle tool. It definitely works. But be sure the right tool is used for the task:-) From first hand experience, this type of tool works extremely well--but it's only as good as the user. You simply cannot press a button and then come back with all the problems solved. It is interactive. It requires intervention and interaction along the way--if you want something practical to emerge. Or unless the problem is simple to start with.

In any case, putting a public focus on this is helpful, I just wish there was a better example given. The analogy to a 'paperclip' had already been made; that's not the best one to be labelled as!:-)

I need to shield radio emmisions from a 5' segment of our dog's radio fence (http://radiofence.com) to let the dog past an area in the garage - other routes I've considered won't work.

I'm thinking running the line line thru a copper pipe will get the job done.

The normal method of wrapping two legs of the run around itself won't work where I need the shield.

Thoughts, comments etc ?

4065. Re: Phased array antenna patterns

RE: Below

One method of eliminating* sidelobes from an array is to use 1/2 lambda element spacing and in-phase, binomial power distribution to the elements.

This has been done in FM broadcast transmit arrays to reduce radiation levels on the ground immediately adjacent to the tower. Paper 5 at http://rfry.org shows some of the considerations for its use. Paper 10 at the same site is a slide show wherein slides 20 and 23 also deal with this.

R. Fry

* in free-space theory, anyway

> Vincent's work. Perhaps you might present an example where a 'new' technical
> subject has been given that much focus at an ARRL sponsored event?

I don't follow any of it. K4WGE made the definitive comment on this
one. "Open podiums gratis: Do as you will with 'em." So K1DFT is
taking advantage of the offer. Whoopie: So what?

> I am of the opinion that it is proper and fitting to have this
venue as a forum
> for Rob's work, but the time devoted would appear to indicate some sort of
> point of view, don't you think?

No. See K4WGE post. All 30 sessions are two hours long. I could get
two hours. You could get two hours. Moses could get two hours.

> Is there, for example, a separate talk by W8JI
> telling us why the Vincent claims are not accurate? Balance would be very
> nice. That is my opinion; yours may differ.

I'm sure the senior antenna gurus will provide plenty of "balance" if
K1DFT discloses his design details at the upcoming session. Until then
balance ain't gonna happen.

> Also, your point is well taken. It would thus appear that perhaps--if there IS
> such a strong interest from the members--

There's a huge difference between idle curiosity and genuine technical
interest. K1DFT's PR apparatus has managed to stir up a huge bunch of
the former at the Popular Science level amongst the membership. It's
gone far beyond just ham radio, it's also popping up all over the
physics and science junkies groups, websites and blogs. So did a
couple 200 MPG carburetor type "inventions".

> that the ARRL do a short, factual, and
> newsy piece on their web site. Otherwise, in an ARRL sponsored event, and an
> ARRL sponsored web page, there is certainly a point of view so cast, don't you

> think, Brian?

No. The posting of a place/date/time of a specific presentation is
simply a news announcement, nothing more, nothing less. Which is the
League doing it's job again.

> I do have a personal point of view, Brian, that is frankly, quite well informed
> and objective. It is not an agenda. I am not an activist.The ARRL has done many
> good things, and it has done others that some feel are more activist oriented,
> and--in my opinion-- not fostering new technologies such as UWB; cognitive
> radio; and of course, BPL.

Uh-huh. Lemme guess: Hams need to dive into cognitive radio so that
ham radio and BPL can live happily forever together in the 2-80Mhz
spectrum. Got it, yessir, we gotta do that. Maybe when pigs fly.

> Hams, in recent years, have little (if any) to show
> in being part of the technological revolution in wireless that has occured in
> the last decade.

(1) The commercials have long since surpassed the abilities of the
basement tinkerers to add anything of consequence to the related
technologies. Why whould Joe Ham futz around with his soldering iron
when he can walk out of a Wal-Mart with a shopping bag full of
wireless technology *and* change from his hunderd dollar bill? (2) I
personally know dozens of hams and I don't know one who is bemoaning
the lack of any type of high-speed comms in the ham bands. The FCC
bent over backward a few years ago to provide space for experimental
spread spectrum ops in the 70 cm band. TAPR launched into a
collaborative SS hardware development effort seven or so years ago.
Nothing. Nada. Zip, there hasn't been a single spread spectrum QSO yet
that I've heard about.

Translation: Meager to nil real interest amongst the proponents,
potential developers and the potential users of wide modes despite the
ongoing volume of whining about the lack of ham development work in
this field.

> It would be a shame if the DLM designs of Vincent were used
> (as a counterexample) in that context for PR sake by the ARRL or anyone
> else--

Makes no sense.

> if, and until, the claims are verified and the technology has been
> demonstrated to offer NEW and UNIQUE benefits.

I agree with that and I don't see where the ARRL isn't also in
agreement.

> I speculate that we will see a full, front page article on the wonders of the
> DLM antenna in the QST September issue, to coincide with the Boxboro ARRL
> Convention. Of course, that COULD be construed as an ARRL 'agenda', Brian.
> And, of course, my opinions may prove to be only partially justified here, and

> maybe totally wrong. Who knows-)?

Calm down Son, you're spring is wound too tight again.

> Brian, do you have a technical opinion on the claims of the Vincent DLM
> technology? I appreciate that you may wish to wait for more data.

No I don't have a "technical opinion" on it, there's not enough
technical info available on the thing to even start to formulate an
engineering opinion. What I do have is a healthy dose of skepticism
and I'll stick with it until such times as this magic monopole has
been thru a collection of independent tests and peer reviews.

I'm too busy to mess with this further = Two-Way exchange over.

'Bye.

>Thanks! You know any simple phased array configurations
> that are easy to mathmatically model?...

In a follow-up to your post Roy, W7EL, suggested modeling an array with his **FREE** EZNEC demo. I'll second that motion. EZNEC is well worth learning to use if one is doing any kind of antenna analysis, even back-of-the-envelope guesstimates.

Here's what I would do to get a high-gain array with EZNEC:

Place a large number of 1/10-wavelength wires in a row, end to end, and separated from each other by 1/2 wavelength. Place a current source in the middle of each, up to the maximum number allowed by the EZNEC demo version. Set each current source to 1 amp at zero degrees. Force each wire to consist of only one segment - this makes the current in it uniform. Have EZNEC evaluate the pattern in the same plane as the wires. This is a one-dimensional phased-array.

You can vary the amplitude and phase of the individual current sources to experiment with beam steering. And you can change the spacing for the individual elements out to 1 wavelength and beyond to see what that does. It's a lot of fun to watch what happens.

This should be a relatively easy configuration to write a far-field expression for if you are so inclined. Math never was my strong suite, so I'm out of my element and can't give you much help. (Hey, we're just a bunch of ham-radio operators here).

Have fun!

Jim, K7JEB

hi john,

Not sure how much you need, try some # 10-2 romex type house wire 25 ' box
at any home depot, lowes or menards, etc. they also cut to length.

Just strip off what you need and plenty for projects.

I have my suspicions too, Chip. Perhaps it
took the other 119 computers and 9.9 hours
of runtime to squeek out that last 0.1 dB of
gain. And maybe this is NASA just showing
that they, too, can do a "SETI at Home" kind
of thing.

Message-ID: <jblzc.173$eM3.27@newsfe1-win>
Source record: 93286

After years of single band mobiling I've decided to invest in a screwdriver antenna. There seem to be 3 of 4 main manufacturers that make these types.
I would be glad of anyone's experience with these antennas.
Thanks
Mike

> forward gain. Where did the extra 15db go?

Well... you won't handle it like that. dB aren't preserved in this
fashion. Power is...

The balloon analogy it good. Poke it "in" at one point so there is NO
radiation in that direction. The signal in the "poked-in" direction will be
really low or zero or MANY MANY MANY dB down...hundreds.

However, try this as another way to see it:

Imagine an antenna that radiates equally well in all directions AROUND the
antenna like an ideal vertical. It will have SOME signal strength in all
directions, which is the same.

Now, lets imagine another antenna (more complex and let's ignore how) which
only radiated HALF way around, but equally distributed, just like before.
That is, it cuts off all radiation to one side as though it was cut with a
knife -- and re-distributes the "cut-off power to the "good" half.
Nothing to the "bad" half -- everything to the "good" half.

The good half just went up 3dB, right ... twice the power.

The bad half went to zero. or infinity dB.

You don't conserve dB.

Help ???

==========

25 watts into a 1/4-wave vertical antenna on 2 meters -

Base current about 0.82 amps into 37 ohms,

Volts about 160, measured (if you can) at top of antenna across about 1000
ohms.

Things vary slowly with length-to-diameter ratio of the antenna conductor.

As conductor diameter increases, volts at the end tend to decrease.

==========

You can please yourself what the accepted value is.

But on the 2 meter band about 1000 ohms is what it actually is.

On the lower frequency bands it runs into several thousand ohms.

As I said, it's a slowly moving function of antenna length-to-diameter
ratio.

But it doesn't matter very much anyway. No need to make a fuss about it.

Hi Bob,

It was derived from a contrivance of math that ignores the loss of radiation resistance. After all, the antenna doesn't exist in a vacuum, and if it did, it would still be surrounded by a medium shorting it out to the tune of 377Ohms.

It's enough to allow that it will bite (the voltage) if you contact it in equally contrived circumstances. Put an NE-2 neon bulb at the end of the antenna to confirm ionizing voltage (60-90V at least). CBers used to do that with their whips with just 5W.

i've used both a high-sierra and yaseu ATAS antennas and both have
been fine choices. the high-sierra was the first model they
manufactured many years ago. that was on the back of my 1st
motorhome. i now use a Yaesu ATAS-100 motorized/multi-band antenna
and it too works as advertised. the ATAS is smaller and easier to
mount but covers only down thru 40m. the newer high-sierra models
require a more heft mounting solution but can tune down to 160m.

> afford that brand.

Is your brother a licensed ham? The FT-857 only transmits in the ham bands
and he would require a ham license to use those frequencies.

> A local dealer is recommending that I buy FT-857 with ATAS-120.
>
> Here are my questions?
>
> 1- Is this combination a good fit and how reliable is it?

The FT-857 is a compact HF/6m/2m/70cm radio that puts out 100W
on HF and 6m, 50W on 2m, and 25W on 70cm.

It has the built-in circuitry to control the ATAS-120 for auto-tuning from
40m up
It does not work on 160m or 80m, though the radio does.

I have that radio and antenna installed in my Ford Explorer and it works
well
for a mobile.

However, if he's not going to be operating mobile, wire dipoles at a decent
height will outperform the ATAS-120, and can be built for a number of bands
for far less than the ~$300 price of the ATAS-120.
(If he's going to be operating mobile, the ATAS-120 works well, with the
limitations
of no 160m or 80m, and its cost is less than many other "screwdriver"
antennas and
the necessary adaptor box to make the FT-857 "think" that they are an ATAS
for
autotuning.)

> 2- Can he communicate with other radios as far away as 3000 miles?

One day a couple of months ago, as I was driving back to my home in
Pennsylvania
from a meeting in New Jersey, I worked stations all up and down the US east
coast
on 40m, then switched to 20m and worked a station in Germany, then switched

to
15m and worked a station near San Diego, California ... propagation varies
and he
would need to select the right band for solar conditions, time of day, etc.

> 3- Do I need a duplexer if he is using just the HF band?

No. There are separate ports for HF/6m and for 2m/70m (a pair for those
combinations. If he's not going to use 2m/70cm, he can just leave that port
unconnected (but would have to be reasonably careful not to accidentally
switch to those bands and transmit with no antenna).

On my Ford, I use the ATAS-120 for 40m-6m and have a separate 2m/70cm
antenna on the same kind of mount on the opposite side of the SUV. That
way,
I don't have to wait for the ATAS to autotune between HF and 2m/70cm if I
want to switch between HF and the local repeaters.

> 4- The radio will be mounted on a land cruiser? Where you recommend
> the antena mounted on?

I used a CP-5M "heavy-duty trunk lip/hatchback" mount and put the pair just
behind the leading edge of the top of the rear doors (the Ford is a 4-door).
The ATAS (and most antennas) will work best up high and in the clear. If
there
are roof racks - and if they are metal and solidly grounded to the body of
the
vehicle, that might also be an option.
>
> Many many thanks for your help.

You're welcome ... just remember, the FT-857 only transmits in the ham bands
and your brother will need a ham license if he doesn't already have one - to
use
the ham bands without a license could get him in deep hot water
(confiscation of
the equipment, heavy fines, and maybe even some jail time, depending on the
country ...)

I disagree.

define how its a failure?

as far as I am concerned, it succeeded. it demonstrated that we can find
useful data in short periods of time using "distributed processing".

sure, no intelligence was located out among the stars, but then, we still
have only scanned less than 10% of the usable sky.

just because we didn't find it doesn't mean that its not there.

Try an electrical wholesaler, though it is likely annealed, not hard drawn.
Also www.mscdirect.com for "Copper Ground Wire" they have 10, 8 & 6 AWG
solid, but in long spools ~$100 each.

Nahhh, let 'em all feel superior due to their "installed user base".
While the whole time they spend more and more of their efforts and
energy fighting off their inferior OS's security holes, we that use the
"non-standard" systems can simply do our work and play.

4103. Re: Beam question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-16 01:12:02 UTC
From: The Masked Marvel <s_crook_remove_underbars_@comcast.net>
Message-ID: <B7Nzc.37558$2i5.13976@attbi_s52>
Source record: 93308

Look at a polar antenna plot (either in the vertical (elevation) or horizontal plane, though horiz would be best for this exercise). The greater the gain *straight* forward the less the angle that the gain is within say -3dB of the peak. F/B ratio is a measure of how much more sensitive it is dead ahead compared to dead behind, and ignores the sensitivity at any other angle, generally (but not always) there will be one large lobe pointed forward and only little bumps in sensitivity to the sides.

Another way to think of it (a thought experiment if you will) is as a garden hose w/ a fine stream out the front (very high gain and very high F/B ratio (very little water shoots straight back at you, and only a small spot that you aim at gets wet, vs. a hose w/ the end cut off and flattened to form a flat fanlike spray -- still good F/B (you stay dry) but the water goes less far and covers a bigger horiz angle. Last, imagine you unflatten the open hose end, point it straight up and hold a plate over it so water sprays in every direction horizontally -- this is an omnidirectional pattern (like a dipole, where RF leaves perpendicular to the wire or element) and goes even less distance (gain) but goes in every horizontal direction. In all cases the same amount of water comes out, but as you change the nozzle you send more in one direction at the expense of all the others. The antenna is the same when transmitting or receiving (collecting if you will) RF energy.

If your hose has some small pinholes in it you may get "side lobes" but they will usually be narrow angled or weak (low gain) -- differant cause than the antenna, but same effect for the purposed of the thought experiment.

Last, if you had a hollow spherical ball much bigger than the hose diameter that fastened on the hose's end and this ball had little holes evenly spaced all over it (and a good imagination) water would go in EVERY direction EQUALLY -- the equvalent of the *theoretical* isotropic antenna.

The analogy is not exact, but it should give a feel of the thing.

Note too some water or RF goes out at an angle from horiz (this is what you see in the vertical plane polar charts) and if you hold th ehose or antenna too close to the ground none can go down (it either soaks into the ground or bounces off and goes upward a bit) giving a slight "takeoff angle" to the beam (or stream).

That help, or only confuse?

I don't normally comment on this stuff, but...

This is not a good way to train a dog; it makes them very
skittish/paranoid/nuts.

I have known several people that have used this method, and every one
has dropped it as ineffective, even if we ignore the cruelty.

I also saw it tried on 2 generations of German Shepherds by a neighbour
around the corner. Both are no longer at that house. No, they weren't
relocated.

It's a bad idea.

Not to start a holy war, but your generalization is wrong.

We are on an acre, our dogs have plenty of room to run, but we have a very busy street behind our house & don't want to risk that one of the dogs gets curious. Further these containment systems are highly effective. We have an Airedale & a Bichon. Both hear the beep before being shocked & head in the other direction.

If we were on a small lot with a large dog I'd agree with you. In my situation, I'd much rather have a skittish dog than a dead dog. As a practical matter, our dogs haven't become skittish as a result of the fence & are much happier than if they were in a pen or on a chain.

Doubt it. EM waves travel the same speed at 1 MHz or 3 GHZ.
If you get a reflection at 3 GHz, you certainly get a
reflection at 1 MHz. All the steady-state shortcuts in
the world won't change that fact of physics. What's sad
is you don't even realize it.

4119. antenna with a tent

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-16 09:18:19 UTC
From: Dr Brain <drbrain@hot.ee>
Message-ID: <40d0104f$1_1@news.estpak.ee>
Source record: 93324

Hi everyone,
as I understand half-wave vertical dont need much of a ground
but it would be nice to have one. And my question: while camping
using a tent that is made from aluminium-coated nylon, could one
use tents inner coating as a counterpoise to half-wave vertical.
Im sure for 1/4 wave this coating would have much too big resistance,
but for 1/2 wave where feedpoint voltages are high it should be ok?
When working from insaid the tent, rig ground connected to tent's
aluminium coating , is it electrically same situation if you were
buried under ground? Is there any performance differences expected
when rig ground is connected to insaid or outsaid of that aluminium
screen. I found this rather confusing..
Any comments?

Do you really want to use solid copper in the antenna? It stretches!
For a long antenna, copperweld would be much better!

Let's not start this again, let's argue about something important,
like Morse code. Ain't enuff of you Apple Suckers and Penguin Pluckers
to be worth arguing with.

We need a new O/S, just for ham radio. We could call it Macnix. The
logo could be a roasted penguin with an apple in his mouth. And there
wouldn't be any application software so nobody would ask questions
about how to use it.....

Chip,
your logic escapes me, or you are reading something into my statement I
did not intend.

my point was, it wasn't proven to be a failure. in fact, the "proof of
concept" for distributed computing was, in fact, quite successfull. how
can you define that as a failure?

Hi OM,

I appreciate this is an interesting topic, so let me conclude and elaborate just a bit.

You changed subjects. Your allusion was to SETI@home. Your comment was to the effect that 'because we didn't find them doesn't mean they're not out there'. Thus you affirm the failure of this premise of searching.

The failure has nothing to do with distributed computing: That is a tool--albeit a useful one--which obviously was used in a ill-posed way and failed to answer a scientific question.

That failure has nothing to do with sky coverage (which you also allude to): it has to do with waveform; high probability of intercept modalities; threshhold S/N; information theory; and so on..

But we're getting a bit too far off topic.

Michael, the screwdriver antennas (most of them, anyway) work quite well.
I would suggest you pick up a copy of "40+5 Years of Mobileering" by Don
Johnson W6AAQ. Don is the guy that designed the original screwdriver, and
he can (and will) sell you one of his, or tell you which of his competitors'
antennas work well, if at all.

Andrus,
The aluminum coating on your tent ~may~ work as (at least 'part' of) a ground system, depending on how large your tent is and how well connections are made. It would depend on the frequency of use (Mhz) naturally. How well it works also depends on several other factors, such as 'shape', just how thick the coating is (if it's very thin, such as with 'mylar', you may have a brief flash and no more coating! LOL).
The size (or length) of the antenna really doesn't make a lot of difference as far as the 'groundplane' is concerned, what would work for a 1/4 wave should work just as well for a 1/2 wave. If your use is in the VHF/UHF ranges, 'maybe'. If it's for HF, there are better ways of doing it...
'Doc

From: Larry Gagnon <lagagnon@fakeuniserve.com>
Message-ID: <10d0n0qtfgl18af@corp.supernews.com>
Source record: 93334

I will be constructing a 135' doublet (14ga. copper 7 strand) fed with ladder line. I am trying to decide what type of ladder line to use:

1) 450 ohm commercial 14ga solid wire
2) 450 ohm commercial 14ga stranded
3) 450 ohm commercial 16ga stranded
4) make my own from 14ga stranded

I am leaning towards the commercial 16 ga stranded, partly for convenience, also I am only running 100 watts or QRP, and I think it might be a bit more flexible in the wind. I only need about 50' of feedline. Any comments from hams who have actually used any of the above and how it faired over the years would be greatly appreciated.

Henry, WD5JFR wrote:
"Shorts can`t dissipate power, so how does a stub work?"

Henry also wrote:
"I know that a shorted 1/4 wave stub exhibits a very high impedance. But for the 2nd harmonic it`s a 1/2 wave stub and exhibits a very low impedance or a short."

Henry is correct.

Connect a resistance directly to a transmitter. How much energy is absorbed by the resistance? Ohm`s law is the first approximation. Current is directly proportional to the applied voltage if the transmitter`s internal reistance is negligible.

The shorted 1/4-wave stub exhibits an open circuit at its mouth and accepts only enough current to supply its losss which are none in the perfect stub. So, it takes no power from the transmitter afer its circulating current is etablished.
At 2X the 1/4-wave freqency, the stub is 1/2 wavelengh and does not transform the short at one end to an open circuit at its other end. Instead, the 1/2-wave directly presents the short circuit at its far end.

How much curent can the transmitter supply to a short circuit? It depends on the internal impedance of the transmitter.

"Transmission Lines, Antennas, and Wave Guides" by King, Mimno, and Wing explains how "Even Harmonics" are suppressed by the 1/4-wave short-circuited stub on page 29. The gist is that the stub is imperfect and its resistance saps harmonic energy which is allowed into the stub by its low impedance.

Best regards, Richard Harrison, KB5WZI

I'm using either 14 or 16 guage solid 450 ohm commercial line, and it
works fine w/100 watts, and has no probems in our moderate climate. I
don't bother to twist it every few feet, and haven't noticed anything
adverse. I'm about to put up a longer dipole with 600 ohm open line to
see if that works even better on a multi-band dipole -- you might add
that to your list of possibles; see www.w7fg.com

Richard, I think you would be surprised if you measured the RF current through the short at the shorted end. It will be the in-phase sum of the forward current and reflected current and is quite high. I once melted the insulation at the end of a shorted 1/4WL piece of RG8X. The heat came from high I^2*R losses at the short.

The SWR inside a perfect stub is infinite.

Does anyone know how much power these wireless units put out out? When I was in the airforce we use to estabish a 3 mile data link with only 10mW. Antennas were 1M parabolic. I still have a couple of these dish antennas that were chunked when the old equipment was updated. A hilltop to hill top link would be a fun project. Maybe something interesting to do for field day.

How far do you want to go? I suspect that putting the high gain antenna on
the base is more practical than on the handset. Of course, your neighbors
might now get free phone service. Also, I don't know where you live, but all
of this is probably illegal, and the Telephone Gestapo will pull your
toenail out.

I have a Panasonic 900 MHz/2.4GHz phone, and the range is a little over 100
m. The 900 MHz direction works better.

Tam

Tesoro wrote:
"Possible or not?"

Depends on line-of-sight path and signal strength.

The radios at both path ends must electrically be in sight of each other. Their powers can be concentrated. The wavelength is 1/8 meter, or about 5 inches.

A reflector, 1/4-wave behind the phone, about 1 or 2 inches, will concentrate the energy in the direction of the phone. A flat sheet of aluminum or aluminum foil will reflect the phone signal in the direction of the phone.
,
A reflector bent into the shape of a corner will further oncentrate the enrgy in its acute angle. A 90-degree corner reflector can give a 10 dBd gain.

Corner reflector angle, driven element spacing, and reflector size and construction are not critical. A side length for the corner reflector of 2 wavelengths, about 10 inches, is ideal according to the ARRL Antenna Book. If skeletal construction is used, the bars in the reflector must parallel the antenna polarization.

Best regards, Richard Harrison, KB5WZI

I want to make a 2m Yagi out of stainless steel, partly because of the corrosion resistance but mostly because I have the materials on hand. Some of my friends have tried to tell me that the higher ohmic resistance of SS will make for a poor antenna. Frankly I do see that it would make any significant difference. While SS has several times the resistance of AL I figure we are just comparing micro ohms to milliohms.at worst, probably more like micro ohm to tens of micro ohms. I am a correct on these assumptions or should I listen to my friends.

From: richardharrison@webtv.net
Message-ID: <8058-40D0996E-89@storefull-3251.bay.webtv.net>
Source record: 93350

Cecil, W5DXP wrote:
"Richard, I think you would be surprised if ypu measured RF current through the short at the shorted end."

I expect high circulating current but without loss not much current is required of the power source.

In his 1955 edition on page 106 Terman says:
"Thus, if the line is short-circuited at the load, then at frequencies in the vicinity of a frequency for which the length is an odd number of quarter wavelengths long, the impedance will be high and will vary with frequency in the vicinity of resonance (i.e., frequency corresponding to quarter wavelength) in exactly the same manner as does the impedance of an ordinary parallel resonant circuit. It is therefore possible to describe resonance on a transmission line in terms of impedance at resonance and the equivalent Q of the resonance curve.

On page 107, Terman gives a 200 MHz example. 2-inch air-dielectric coax is used for 1/4-wave short-circiuited stubs about 15 inches long. The resonant impedance is more than 250,000 ohms with a Q of 3000.

How much current flows into an impedance of more than 1/4-million ohms?

Best regards, Richard Harrison, KB5WZI

4145. Good 144/440 mobile antenna recommendations

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-16 19:06:04 UTC
From: kb@shadowstorm.com
Message-ID: <40d099af.21415784@127.0.0.1>
Source record: 93349

Can anyone recommend a good mobile 144/440 MHz mobile antenna to use
with a Yaesu FT-7800R (50 watt) mobile rig?

Thanks,

Michael

Gad Danny. Why are you promoting getting my stuff there. I've
politely asked him to remove my papers from his site but never even
got a response.

Had he actually asked for permission, I would have gladly given it,
although he, as did I, should also ask ARRL since they hold the
copyright. As it stands, he *does not* have permission to have the
material on his site. (Could this be the "Phil" of Fractenna fame?)

Hi Adrian,

I read your last post, and some of the replys, but from what you discribe
they don't sound like the G-whips I have,

Mine are a single coil and whip for each band.

Are you sure they are G-whips ?

Steve.

I just want to visit the neighbours within 50 or 100m of my home. Seems as
though I can't get good reception even 3 houses down (30m?). I was thinking
if it was possible to add an outdoor type antenna to boost the range. I
thought I should be able to go at least a few houses away but I was wrong.
Thanks for your reply...

If you have the materials go ahead and make the antenna. SS is just harder
to work with for most people and weighs more. YOu will loose some gain but
unless you are into very weak signal work it will not be too noticable. I
have an 8 element quagi for the 220 mhz band I made using SS welding rods
for the directors. It works beter than a 6 element beam I had up in the
same place. It also works much beter than the 11 element CC antenna that
was also in the same place.

Use the SS. I just finished building a dual band J-Pole 2m/70cm and
used SS. It works just fine. 2m SWR ranges from 1.0:1 to 1.4:1 and I
have had great success hitting distant (40 miles) repeaters on ~5w at
only 20' AGL at my location, but about 5' BELOW average ground level
for the entire city... Go figure, I bought the place in the bottom of
the hole! :)

Yeah, now I can amaze all my friends and co-workers. All I need to do
now is get some of that "male enhancement" Enzyte and I'll probably be
CEO by next month.

What I was looking for was really this: tangent loss and dielectric
constant are the two main factors that determine RF propogation
properties through a material.

Depending on the card, and whether you have twiddled any special
registers in it, up to around 100mW. I believe the current distance
record from the contest they have every so often is around 50 miles.
People regularly do 10 to 20 miles.

Antenna plans, as well as manufactured antennas, and bidirectional power
amps are readily available. And may or may not be legal, depending on
many things, like if you are a ham using the correct (lower, I think)
channels, etc, etc.

I have a couple 2.4GHz bidir amps plus patch antennas at work that we
just recieved to play with. Haven't fired them up yet. Yes, they are
legal in this case, and we are also a wireless (and wired) ISP.

If you want to play with a good Access Point, get a Linksys WRT54G, and
flash it with the modified version from Sveasoft. This greatly enhances
the capabilities, adding such things as ssh access, kernel based
stateful firewalling, full routing capabilities, traffic shaping, etc.

In that frequency range, it is almost purely line-of-sight. Anything
from VHF on up, the higher the transmitting antenna, the better the
range will be. If you have a second floor, put it up there and you
should get the range you want, although some building materials will
interfere.

4161. Re: Shorted 1/4 wave stub ?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-17 01:03:46 UTC
From: Cecil Moore <w5dxp@hotmail.com>
Message-ID: <40d0ef30_2@corp.newsgroups.com>
Source record: 93366

Richard Harrison wrote:
> How much current flows into an impedance of more than 1/4-million ohms?

As you know, transmission lines transform impedances. That stub likely has an SWR around 5000:1. Assuming a driving voltage of 250V, the current at the 1/4-million ohm point is about 0.001 amps. However, 1/4WL away, at the short in the 1/4WL stub, the current will be ~5 amps with a voltage of ~0.05V. That's an impedance of ~0.01 ohm. The shorted stub has transformed the impedance from 1/4-million ohms at the mouth to ~0.01 ohm at the short. That's what transmission lines do.

The question is not, "How much current flows into an impedance of more than 1/4-million ohms?" The question is: How much current flows 1/4WL away from that point at the shorted end of the stub? The answer is the sum of the forward current and reflected current. The voltage at the shorted end of a 1/4WL stub is the difference between the forward voltage and the reflected voltage.

The voltage at the mouth of the stub is the sum of the forward voltage and reflected voltage. The current at the mouth of the stub is the difference between the forward current and reflected current. In the example above, that difference is ~0.001 amp. The forward current flowing inside the stub is ~2.505 amps and the reflected current flowing inside the stub is ~2.495 amps.

If you don't believe the above, simply measure the RF current at the shorted end of the stub. Someone modeled it the other day and even the modeling program indicated that the current was sky high at the shorted end of a 1/4WL stub.

I beleive the FG stuff is only 16ga so yes, it would have a bit more resistance loss but the design would lessen the effect of moisture however it would be harder to install since it has fewer spreaders. Probably better to make your own line. Much more fun!

Cecil, W5DXP wrote:
"Someone modeled it the other day and even the modeling program indicated that the current was sky high at the shorted end of a 1/4 WL stub."

Agreed that the resistance of the short is small and allows a large current even when the volts are low. The small load resistance, ZL is transformed into another resistance, ZS that is inversely proportional to ZL. Terman expresses this in equation (4-31) as:

ZS = Zo squared / ZL

So, the smaller ZL, the larger ZS. As ZL goes to zero, ZS goes to infinity.

A high impedance means: accepts little current for a given voltage. The open end of a good 1/4-wave short-circuited stub is defined as a high impedance. So much so that it is also called a "metallic insulator".

Best regards, Richard Harrison, KB5WZI

It has spreaders positioned every 20". The two lines are 3.75 inches
apart, which gives 600 ohms, according to a table I looked at in one
of the antenna books.

If it was indeed a high physical impedance, like a 250K resistor, it could
be removed and no much would happen at its resonant frequency. Unfortunately,
it is not a physical impedance and is merely a V/I ratio, a virtual impedance.
There is nothing at the mouth of the stub capable of causing reflections.
All the reflections occur at the shorted end of the stub.

The forward and reflected voltages add in phase and the forward and
reflected currents add 180 degrees out of phase at the mouth of the stub.
The ratio of forward voltage to forward current is the Z0 of the stub as
is the ratio of reflected voltage to reflected current.

You are absolutely correct, but that wasn't the "strange URL" I meant. The
post
that started this thread is as follows (from June 12):

<quote>
The information about filing a FCC BPL comment on the ARRL web page was
outdated. There is a new case number that should be used. 04-37 is the
correct case number.

It only takes 5 minutes to file a comment with the FCC against BPL.

http://vambo.org/a/
<end quote>

Somebody else questioned it first, wondering why the FCC URL wasn't just
posted;
then somebody brought up paranoia. I seconded the paranoia and I stand by
it, at
least in principle.

vambo.org, searched on google, gave me no obvious ham radio links but a
little digging
identifies a Colorado ham associated with the site. (By "digging", I mean
google &

qrz.com; no hacker weapons here -- I'd probably shoot my eye out :-)

73,
John
KD6VKW

PS: While I was composing this, Norton Internet Security intercepted a
trojan attempt.
Who's paranoid? I am.

That's correct - especially the last part.

In typical yagi designs, resistive losses in normal aluminum elements
are on the order of a percent - which is negligible. There are many
grades of SS, of course, but again a typical value might be a few
percent.

In Europe there is a successful range of 'Flexa-Yagis' of very
lightweight construction using elements made from thin, springy SS wire.
These yagis are only about 0.5dB down in gain compared with ali elements
at 144MHz, and maybe 1dB at 432MHz.

A few years down the line, when ali elements may have corroded, the SS
elements may even come out ahead.

Look at all the mobile antennas. For the most part they are SS. Mainly
because of the stiffness of the material. The antennas for the low bands
are usually not SS. Part of it is that the short for wavelength antennas
can not stand much resistance where it becomes a large part of the overall
"radiation resistance".
When the antenna is aproaching a 1/4 wave or more the resistance of the
material it is made of is less important.

Forget about a ground rod. A single ground rod makes a very poor earth in any sort of soil except salt water. It is no better than a shallow buried radial wire of the same length.

You can have a good ground with a relatively small number of shallow buried radial wires. Begin with 6 or 8 radials about 1/8th or 1/10th wavelengths long. Then increase number until RECEIVED signal strength from several stable transmissions stops increasing each time the number is increased by 50%.

Jimmie

How much power can you produce at 2 meters?? If you or your friends can
put enough power into a stainless steel dipole, you can get a pretty good
idea of the power its disipating by monitoring its temperature rise.
It might be interesting to ask your friends for any of the data they have
for determining their advice to *not* use stainless. They could be right.
But, sometimes inaccurate rumors get spread and get intermingled with truth.

Jerry

Correct, if the generator matches Zo. In any case, Zo limits current on the transmission line until a reflection from the mismatched load arrives back at the line input to change the impedance seen by the generator. Then, the current delivered by the generator will depend on the generator`s match to the new impedance caused by the reflection after a few iterations.

Another view of the mismatched line is to ignore what the transmitter can deliver into any load. Then, the forward and reflected waves simply cause a current in each direction depending on the strength and the current allowed by Zo.

Transmission lines are tyrannical in forcing current in a particular direction to adhere to the Zo voltage to current ratio. That`s the reason a junction between lines of differing impedances produce a reflection. The line from the source contains a voltage wave and a current wave conforming to Zo. The line of a different impedance connected to the line from the source accepts alll the voltage or current available to it which leaves a surplus of either voltage or current that must be reflected back toward its source. The source line is no less dictatorial about its Zo to the reflection than it is to the incident wave.

Best regards, Richard Harrison, KB5WZI

The corrugations may add length and inductance that is difficult to account.. Otherwise it is something I have never given much thought to as I have always used smooth materials to wind coils. I have noticed that when using a threaded rod for a radiator on 2 M the antenna worked out to be a little shorter than expected.

ANYTHING which slips over an omni-directional antenna will make it more
directional. You can't have net negative directivity.

Where are your customers?

Microwave waveguide is just an infinite number of 1/4 wave stubs connected
mount to mouth.

This is very interesting! I had wondered about that myself! If
static is dissipated more efficiently on a sharp point, would an
antenna with a vertical with a needle point on the end tend to radiate
more energy in the vertical direction?

I have no clue about antenna performance in this situation. Just a
curious question really!

Actually I prefer working with SS over Al. Screws and pop rivets hold
better. I can braze/weld it easdily and SS holds up better while working on
it than Al(ie I just deformed a piece of Al while using a tubing cutter on
it, no such problem with SS. Yes I see how weight coud be a problem but will
limit this to UH/VHF antennas

Yes, I was wondering if would affect the inductance per unit length or maybe
adding distributed loading for the new historic design that is in the works.
I think it would take somebody well versed in 'Fields and Waves' to obtain
an authoritive answer on whether the field generation vectors would cancel
in the valleys
or bend and add to the generated field. I suppose the same question could be
applied to the use of a spring design that was then wound in a inductive
form possibly to obtain constant current flow over the physycal length as
opposed to the actual electrical length hich may well be more than 4 times
as long!

How is that possible, considering that a rectangular waveguide operates well in single mode over about a 1.5 to 1 frequency range, and has a different field distribution than a transmission line (TE01 vs TEM)?

Henry, WD5JFR wrote:
"Microwave waveguide is just an infinite number of 1/4 wave stubs
connected mouth to mouth."

It`s true that a waveguide is the same as any number of shorted 1/4-wave shorted stubs connected in parallel. Their parallel connection between the same two points will not affect their resonant frequency. That`s why, as Richard Clark noted, if the 1/4-wave shorted stubs are circled around into the form of a closed container, it makes a resonant cavity. The diameter of the drum formed by the large number of 1/4-wave stubs has a diameter of 1/2-wavelength at the resonant frequency.

Rectangular waveguide is more or less aperoiodic down to the low frequency limit of its propagation. This occurs where its larger cross-section dimension is 1/2-wavelength. Attenuation rises as frequency through the waveghuide is lowered towards its cut-off at the 1/2-wavelength dimension. Below cut-off, attenuation is very high.

In the waveguide`s passband it is preferred to coax because air-insulated coax has about 3X the loss of waveguide. But, waveguides must be at least 1/2-wavelength wide which limits practical use to microwaves. A waveguide for 30 MHz would be at least 17 feet wide.

Best regards, Richard Harrison, KB5WZI

Hello,

It's always funny to see people saying, "best I have ever used" etc, what must they have used before!
It's not really a new design is it, maybe just similar to what is known as a "nest of dipoles" that scanner enthusiasts have. They use different radiating elements in parallel.

Hi Jason,

Not that at all, otherwise all of the elements would be driven, and simple observation negates that. I've reported a similar design to this group years ago that uses the SO-239 bulkhead connector wired up in similar fashion: One wire extending directly from the center pin solder tail, and another wire, parallel, soldered to any of the four holes normally used for mounting. No need whatever for the usual JPole tuning cap.

There's an analysis of a similar design on Cebik's web site - his
"non-standard J-pole" is a bottom-fed, non-shorted design with a
shorter-than-usual radiating section and a longer-than-usual matching
leg.

http://www.cebik.com/jp1.html

It looks to me as if the Arrow design has similar element lengths to
the one which Cebik models. The Arrow trick of using one element as
the matching leg for 2-meter and as the radiator for 440 is a slick
one.

Everyone I've spoken with who has used an Arrow 146/440 J-pole has
been very happy with it.

Hi Jason, Dave,

A repeat of a subset of data offered here 5 and 7 years ago from data
measured at the bench 12 years ago:

... built up from 0.085" diameter bronze tubing. In each case, the
center connection is brought out 13 inches.... with one vertical
element that paralleled the main element with a constant separation of
0.5 inch.

The variation of the second rod is called "Match Length" in the chart

Radiator Match Fo SWR
Length Length MHz 50 Ohm

13.0 6.0 485 2.8
13.0 5.75 548 2.3
13.0 5.5 556 1.8
13.0 5.25 576 1.8 (545-630 < 3:1)
13.0 5.0 624.5 1.48 (575-640 < 2:1)
13.0 4.75 638 1.08 (640-660 < 2:1)

I actually have met John and spoke with him in person about this on
Monday night. The wire is for a small 2M beam for DFing. It needs to
be quite stiff and increased diameter will make for better B/W.

Mike, don't even bother with burying anything then, use above ground
radials. Others here have run tests of various heights above ground, from on
it up to the antenna itself. Many seemed to work quite well if I recall.
Maybe someone in the group could model an idea of your available design. For
other applications you could also use a tuned(tuner) counterpoise.

4214. best stealth antenna for a 50 foot tree?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-18 05:33:16 UTC
From: eternalsquire@comcast.net
Message-ID: <904dab11.0406172133.586c6e39@posting.google.com>
Source record: 93269

Hi,

I'm moving again, this time to an apartment complex where formally antennas are forbidden but informally the apartment management doesn't mind shortwave listening so long as the antenna is discreet and has no permanent attachment. The good news is that it is on the ground floor, and my window is only a few feet away from a 50 foot acacia tree. I live in a desert environment, and so the acacia is extremely straight with short branches (but LOTS of thorns!).

I need to keep the antenna as inconspicuous as possible, and I have the informal nod from my apartment management so long as I keep my promise that the wire will be invisible beyond about 2-3 feet. I'm planning on using number 30 kynar wire-wrap wire with insulation color as closely matched to the tree or to the apartment housing walls as possible. I'm not intending to operate more than about 20-50 watts.

I'm thinking the best idea is a wire vertical as high up in the tree as possible, or possibly an interted vee. How much base would I need for an effective inverted vee, anyway? For counterpoise, there is a long thin metal strip landscaping barrier extending for at least 100 feet in either direction, which is about 10 feet away from the acacia tree. One side of the strip contacts sandy soil, the other side of the strip contacts lawn.

I could anchor the inverted vee to the bases of a couple 30 foot trees on either side of the acacia that are about 10 feet away. Or, I could simply anchor the kynar wire with a pushpin to the base of the acacia and feet with buried submini coax to my window a few feet away.

I'm a little bit scared of using a slingshot to throw a wire into an acacia tree, because the branches are so short. Would it be feasable to slide multiple sections of PVC rod along the side of the tree just to gently place sinker over the top branch?

So, I have a decision to make, but I am not sure which would be the best one.
I am surrounded by many houses and lots of trees, which could get in the way of the signal.

Please advise,

The Eternal Squire

It will be fragile, but the difference between it an #12 hardly amounts to more than a half dB.

Sounds fine.

A variation, but perhaps too elaborate for not much gained.

>I'm a little bit scared of using a slingshot to throw a wire into an
>acacia tree, because the branches are so short.

I can't see any downside to this except you could over-power the wire and snap it sending the weight flying beyond its intended target. It is VERY easy to snag a loop as it climbs up and if the wire holds, you could find that weight recoiled into your kisser (been there).

The right way is to scramble fill a bucket with loose loops of wire (or monofilament, or braided nylon - NOT twisted). The bucket serves as a low friction feed and the random fill of loops keeps snags to a minimum.

>Would it be feasable
>to slide multiple sections of PVC rod along the side of the tree just
>to gently place sinker over the top branch?

Not if you want to be inconspicuous about it. ;-)
Your neighbors will appreciate the humor in the old joke about one-armed paper hangers.

>So, I have a decision to make, but I am not sure which would be the

This is NOT a problem for HF. (Simply because there is nothing you
can do about it anyway. In terms of real numbers, ï¿½3dB, it is still
no particular problem.)

I am using the W7fg line. In my opinion its major advantage is the teflon
insulation.
I might note that the horizontal part of the160 Meter doublet which uses the
16 ga wire
(about 240 feet + feed) broke many times at the insulators . I replaced the
doublet part with #10 copperweld and so far no problems. This could have
been because of high winds, attachment to
trees (even with pulleys and weights). This was inconvenient to say the
least.
No problem with the feed line however.

Al gave me one for testing many years ago. Using my Palomar FS1,
it tested out better than a 1/4WL and equal to a vertical dipole.
I also modeled it using EZNEC with the same results. It is still
going strong although, after a decade, the plastic end caps have
cracked in the AZ and TX sun. Honestly, that's the only criticism
I can think of. Those end caps are of only cosmetic value.

I just put a wire into a 70ft high oak tree with a slingshot and fishing rod. Place the fishing line over the target branch then pull up some nylon twine. You can use that to pull up the final wire. It may take you several shots to get it where you want, so just use some old nuts and bolts for weight. Forget the coax and run the wire straight into your antenna tuner.

Just worked KH6 on 40cw last night with 100w ... works great!

"quite stiff" as in self-supporting? Don't want plain copper wire
then. Even #10 copper wire will barely self-support in lengths
suitable for 2m antenna. Any weather or bump and your antenna will
need to be straightened. In the same aisle at the hardware store
they probably have bare copper up to #4 or #2. Much stronger. And
not much more money in the quantity needed for a small 2m beam.

He may want to consider using 1/4" soft copper tubing for the
greater diameter. One could, I imagine, fill the tubing with
something if it needed to be self-supporting. Or else just use
small diameter rigid tubing.

Agreed. I'd be tempted to try brass tubing, available from good hobby
shops - it's light and rigid.

There are some very effective DF/foxhunt antenna designs on the Web
for which the elements are pieces cut out of a scrapped steel
measuring tape. The material is light, quite stiff when it snaps out
into shape, and can survive numerous whacks and bends without
suffering permanent deformation. I'm sure its electrical losses are a
good deal higher than for copper, but unless you're DF'ing really weak
signals I doubt that this would be a problem. Just make sure you put
some sort of protective coating or cap over the cut ends... they're
sharp and could easily scratch / cut / put-out-an-eye!

No comment here on the installation and configuration issues which Mr. Clarke addressed quite adequately but with respect to the wire itself you might consider a look at a very durable #26 "thornproof" (it sez here) and near-invisible alternative:

Good evening to all. I just received a ten tec scout 555 and hooked it up to my 58 foot attic dipole through an MFJ 901b and RS swr/pwr meter. On the rs meter I am reading infinity for swr at roughly 30 watts on cw (really only mode I use) on 40 meters. On the scout meter, I am reading at most, 2:0. Now the scout has an adjustment on the bottom for power. With the radio on, into a dummy load, as I increase wattage, swr goes up and the ALC light goes out. I am not sure how to explain this but . . . when I try to tune the rig through the tuner, the meter light dims and a lot of humming is heard through the phones. The cw tone is purest when I am running about 8 watts. There is no hum, no dimming light, and the ALC light remains lit. Basically, do I need to get a better tuner, power supply(rs 3A ps in currently in use), or something else. Thanks for any opinions.

Al, where can I get that piece here in Europe??
How about the different Frequency range for our Region? 144-146 and 430 - 440?

4233. How to Measure a 2M Yagi Impedance?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-19 09:05:46 UTC
From: "Paul (Home) News" <pmcmahon@telstra.com>
Message-ID: <KITAc.43499$sj4.34204@news-server.bigpond.net.au>
Source record: 93188

Hi,
I have done quite a bit of numerical analysis of VHF Yagi's with usually very good agreement between theory and performance at least for gain and pattern. One of the things that seems more difficult to correctly predict however is the input impedance, and thus to design some sort of a match without some sort of subsequent trial and error. In an effort to explore the differences further I have been looking at ways of measuring the impedance directly rather than indirectly by vswr with the matching in place. I have made a number of different return loss bridges, and even tried the technique described in an old Ham Radio Article where you take two VSWR readings with and without an added series resistance. All of course making allowances for coax length etc. The problem I have is all of them give, in some cases wildly, different answers even when used on the same antenna. So my questions are:

What sort of accuracy can I expect from these sorts of methods?

Is there a better way (which doesn't involve large sums of money) to measure antenna impedance at say 146Mhz?

Thanks

Paul VK3DIP

Hi Greg,

The Scout is very fussy about it's power supply you need one capable of
at least 10 amps. Also it very fussy about the voltage underload it
will act up whenever the voltage drops to about 11 or 12 volts. This
would be my first step. Get a better power supply I used a scout for
many years it's a great little rig. And the folks at Ten Tec are supper
at helping you out. So if the problem persists after you've upgrade the
power source give them a call.

Also, try someone other than RS for your supply :-) You want one
that's filtered against hash -- a quiet supply appropos for
communications gear. See your local ham dealer or places like AES or
HRO.

==========
Paul,

Attempts to accurately determine antenna input impedance, using an
inherently ambiguous, innacurate SWR meter at the transmitter end of a line
of uncertain length and velocity, are doomed to failure.

Never expect to obtain numbers worthy of serious engineering application.
There are far too many uncertainties of unknown magnitudes.

The only way of obtaining an accurate measurement is to climb a ladder
taking with you an R plus or minus jX hand-held impedance bridge. Can you
borrow one ?

But why do you wish to know antenna input impedance when you are aleady
quite happy with using an inaccurate SWR meter to fiddle a 1-to-1 SWR at the
transmitter end.

The ultimate objective, of course, is just to obtain a 50-ohm load for the transmitter regardless of what the SWR and antenna impedance might be.

Source record: 93192

The input impedance can be measured reasonably well at ground level.

Align the antenna so that the reflector is 'down' and the last director
is 'up'. Ground effects are minimized due to the F/B of the antenna. The
antenna is radiating straight 'up'.

Next take a 1 wavelength, allowing for velocity factor, coax line and
connect it to the antenna feedpoint.

Finally, beg, borrow, requisition, pilfer, rustle, etc., an antenna
analyzer similar to the MFJ 259B. Connect it to the other end of the 1
wavelength coax.

Select the function to read impedance. Dial in your frequency and read
the impedance.

A one minute job once the antenna, coax and meter are at hand.

4240. Dr. Vincent's DLM antenna...

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-19 18:35:48 UTC
From: "Peter O. Brackett" <none@no-such-domain.nul>
Message-ID: <8I%Ac.7189$bs4.3831@newsread3.news.atl.earthlink.net>
Source record: 93195

In 14 June EE Times on page 55 we find an article on a new concept in "miniaturized" antennas following are a few titilating quotes which I have excerpted from the article. The article may be available from the EE Times WWW site: http://www.eet.com.

"University researcher calls distributed load monopole a radical take on old ideas"

"A four year skunk works effort at the University of Rhode Island in Kingston has cut the size of an antenna by as much as one third for any frequency from the kHz to the GHz range" Using conventional components..."

"I've been able to put a combination of them [old ideas] together to create a revolutionary way of building antennas. It uses basically a helix plus a load coil"

"a completely planar design is less than a third the size of today's cell phone antennas"

"And those 300 fiot tall antennas for the 900 kHz AM band that dominate the skylines would only have to be 80 feet high"

"When looking at these antennas, you pretty much have to forget everything you ever knew about antennas and keep an open mind, because some of the things I have done are vey radical"

"I reduce the inductive loading that is normally required to resonate the antenna by as much as 75%... by utilizing the distibuted capacitance around the antenna"

"it's a two dimensional helix"

"the current at the top of the antenna is 80% of the current at the base"

"Vincent said no existing modeling software could adequately model his antenna design. So he rolled his own simulation with Mathcad"

"Eight years ago antenna design was 90% black magic and 10% theory, said Vincent. But now with my design they are 10% black magic and 90% theory"

etc... etc...

Apparently Vincent received the 2004 Outstanding Intellectual Propery Award from the University of Rhode Island's Research Office, joint applicant for the patent.

Sounds fantastic I want one of these 90% black magic antennas for myself!

But, it smacks of the "fractal" hype, maybe it's just too good to be true?

The inventor is one Dr. Robert Vincent of the Physics department of the University of Rhode Island, Kingston, RI which apparently will share the "pending" patent with him. Vincent is a radio amateur [No call sign given in the EE Times article.] and claims he got the idea for his radical new antenna designs while trying to satisfy his neighbours complaints about the size of his 140 foot 160 meter antenna and so he ultimately came up with a 46 foot "DLM" antenna that was equally as good.

As usual with EE Times little or no technical detail was given!

Anyone know anything about this DLM antenna.

Comments, thoughts...

In principle it can be done. But to determine antenna impedance from measurements (NOT SWR) made at the transmitter end of the line it is necessary ACCURATELY to know the Length, Impedance Zo, Attenuation and Velocity Factor of the line.

Line attenuation need not be known with high accuracy. But, obviously, with a longish line the information available about what is going on at the far end becomes degraded. And to rely on measurements made with an ordinary, ambiguous, inaccurate swr meter, as you have already found, is asking for trouble.

Measure input impedance, R+jX, of the line. Then use program ZL_ZIN to calculate what the antenna input impedance, R+jX, must be to provide such an input impedance.

I havn't looked at the program recently but I think an ambiguity can arise if the whole number of half-wavelengths in the line is not known. So it may help to have some idea about what's going on in the process. But you'll know when you get the right answer.

Program ZL_ZIN can be downloaded in a few seconds from website below and run immediately from its desktop icon. It's easy enough to use when the input data is known.

From what I've seen at Lowe's you'll do okay if you intend to make it
from copper pipe - but that would get pretty heavy. If you want
aluminum tubing you might check Texas Towers or look for a local
'industrial' supplier such as Tiernay which has been acquired by
Transtar.
http://www.tiernay.com/

Good Luck,
Howard

Let's see, 0.27 of a full sized design. Planar AM antenna?

>"it's a two dimensional helix"

Let's see, how many bottles of wine could you open with a two
dimensional cork screw?

>"the current at the top of the antenna is 80% of the current at the base"

If you couldn't get any current into the base, this could be a
problem.

>size of his 140 foot 160 meter antenna and so he ultimately came up with a
>46 foot "DLM" antenna that was equally as good.

Let's see, 0.33 of a full sized design. It would be smaller yet if it
were Planar. Equally good (ï¿½3dB)? Now there's a specification to
match!

Confirming the observation of 9 out of 10 lab-coat wearing scientists,
the presence of a three letter acronym (Appellation gain) provides
this remarkable benefit of size reduction (fewer letters) that varies
to suit the occasion.

>"Vincent said no existing modeling software could adequately model his
>antenna design. So he rolled his own simulation with Mathcad"

As for the benefit of other Appellation gain (Dr.) there is an obscure
(broken link) reference to: "Gravity Waves and their Relationship to
Interannual Variability in the Tropical Pacific, by Dr. Robert
Vincent, Department of Physics..." Another astronomer re-inventing
field math?

What continues to amaze me, that in the supposedly most high-tech nation on Earth, is the high proportion of suckers, amongst them professionals, who still fall for such stuff.

Even Hertz and Marconi knew better.

Heaviside abandoned the system at a very early age.

Praps its all due to the system still being in the hands of marketing, sales and advertising departments.

Or have I misunderstood the context?

Reg.

> I have considered just burying several strands of heavy bare copper wire and
> using that for my ground.

The other answers confused an RF ground with an ELECTRICAL ground. For better antenna usage, above ground, on the ground or in the ground radial wires are the best thing. I have read several articles describing the optium length for a radial, some go as short as 1/4 wave * velocity factor, one went as long .28 wavelength. YMMV. Actual diameter of the wire is not very important.

However you will still need an ELECTRICAL ground for lightening saftey and static discharge. That should be as wide and as deep as possible. If you can only go down 1.5 feet, then a 6 foot length of 1" copper pipe layed horizontaly as far down as you can go would be a good idea. Ask a local electrician.

You don't need to worry about wetting it or adding conductive agents to the soil unless you have lightening storms when the ground is dry. Although I live in the desert, I don't. When there is a lightening risk, the ground is damp.

Geoff.

McMaster-Carr, online catalog has so much stuff plus lots of info on the
items,
good section on metal tubing and the types and grades available.

Good source for ss bolts and other hardware too.

I use them for aluminum rods, they ship fast from many dc over the usa.

As is so frequently the case, David has the scheme. Long, long ago at Green Bank, I worked on a 400 MHz feed for the 85 foot dish that consisted of two dipoles fed in phase above a reflector. Since this was for radio astronomy measurement, it was desired to have a good match at two frequencies 60 MHz apart to use with a receiver having a 30 MHz IF. ("signal" came in both images.) I worked on the stubs with the antenna feed pointing away from me in a very large room while measuring with a GR admittance bridge. The bridge is adjusted for a null while listening through headphones.
While thinking about the next adjustment, I heard the sound in the headphones go out of null and then back. Eventually I traced the in-and-out to secretaries walking back and fourth around a table to collate a report in a room way across the empty lab and on the other side of a thin wall. Energy coming back to an antenna changes its apparent Z.
Quick-like-a-little-bunny, as we say in these parts, the feed was put on the top of a step ladder outdoors pointing at the sky. When adjusted while up on the ladder, it worked as expected when placed at the focus. But that is another story.

Hi Paul

Gordon VK2ZAB (and others) published some time ago a complex Z bridge
thing for VHF/UHF. It uses transmission lines for tuned elements and is
band specific.

Try http://www.vhfdx.oz-hams.org/measurements.html

And do other google searches using Gordons callsign

Cheers Bob VK2YQA

SNIP Reg, I did not specify the transmitter end of the line. I stated 1
wavelength from the antenna. In this case, 1 wavelength, the line
impedance is not a factor, but the velocity factor is.

Line attenuation at 1 wavelength at 146 MHz is generally negligible. I
did not use the SWR meter. I stated use an antenna analyzer.

I think the confusion arises because your reply is to my post and not
the original post.

Dave, I was replying to the original questioner. But by immediately following your response with mine and including a comment of yours caused a little confusion. Sorry!

I agree your method will work. The problem, a practical one, is obtaining a COAXIAL line length exactly an integral number of 1/2-wavelengths long. There's no way of proving it exept by climbing a ladder and disconnecting the line from the antenna.

And it is an exact 1/2-wavelength long at ONE frequency only. But it is required to make measurements over a whole band of frequencies. To shift to other frequencies
involves calculations taking Zo into account. But Zo is not accurately known. So then you have to measure line Zo. And so on.

And you have to know exactly what you are doing because the 259B does not provide the sign of jX in R+jX.

But as I said before, all you want to know is whether or not the transmitter is loaded with 50 ohms. To hell with SWR and antenna input impedance. ;o)

Reg, G4FGQ

Okay, the antenna is 66 percent of *some* antenna.....

> "I've been able to put a combination of them [old ideas] together to create
> a revolutionary way of building antennas. It uses basically a helix plus a
> load coil"

That really isn't terribly revolutionary, is it?

> "a completely planar design is less than a third the size of today's cell
> phone antennas"

So now it's 33 percent of the size? And are all these antennas a third
of the size of todays cell phone antennas?

My point is this is criminally inaccurate writing. Does the good doctor
know that people are writing so poorly about his good work?

> "And those 300 fiot tall antennas for the 900 kHz AM band that dominate the
> skylines would only have to be 80 feet high"

Which is that... 66 percent, or 33 percent?

> "When looking at these antennas, you pretty much have to forget everything
> you ever knew about antennas and keep an open mind, because some of the
> things I have done are vey radical"

Is this like esp or bending spoones, where if you don't keep an open
mind, it won't work?

If the antenna works, it will work whether we have an oen mind or not.

> "I reduce the inductive loading that is normally required to resonate the

From: yea right <spam@spam.spam>
Message-ID: <pan.2004.06.20.02.17.24.921719@spam.spam>
Source record: 93213
Cross-posted to:
rec.radio.amateur.antenna,rec.radio.amateur,rec.radio.amateur.digital,rec.radio.amateur.digital.misc,rec.radio.amateur.dx

"The limit for an unintentional emitter on HF is 30 uV/m at 30 meters from the source," he said. "If you take a dipole cut for 3.5 MHz and put it in a 30 uV/m field, you'll have a noise reading of S9 plus 16 dB at your transceiver."

The FCC has extended the comment period for BPL. If you value radio, this may be the last and only chance to have your voice heard to stop BPL from destroying your hobby. The FCC has extended the comment period for BPL.

It is VERY simple to file a FCC comment. Click the link below and enter

04-37

in box #1 (proceeding number) and fill in the blanks. The simplest way to comment is to type your comment into the box on the bottom of the form. Sample comment below.

http://gullfoss2.fcc.gov/prod/ecfs/upload_v2.cgi

If you see fit, please post this to as many groups as possible because numbers count! Please mention this in your nets!

More info at http://www.arrl.org/news/stories/2004/02/12/5/?nc=1

If you can't think of any thing to type or wish to make this as painless as possible, you can cut-n-paste the comment I typed below.

/******************************/

In Writing, I wish to persuade the FCC from allowing BPL to be implemented. The destruction or at the least, deterioration of the shortwave bands is not only a violation of ITU laws that protect international broadcasters from interference and jamming, it will be destroying many people's life hobby. Amateur radio will be reduced to users with high-power amplifiers and large antennas. Emergency communications will be hindered to levels directly responsible for the loss of life. Also, this will hinder military HF comms reducing national security

There are many technologies that make BPL unnecessary. BPL will never be able to carry the high bandwidth demands for mass distribution of video much less the up-and-coming HDTV.

Thank You!

It's not really. Maybe compared to aluminum...I built a 6m 3 el totally from copper, including the boom, and it's really not that heavy at all. Might be twice?? aluminum, but a 3 el aluminum beam would be super light.
4-6 elements from copper could be handled ok. Must use hard drawn copper though. If you used 6 elements, I'd use a real thick boom, if also copper...For 3 el, I used 1/2 inch for the elements, and 1 inch for the boom. With the usual 10 ft lengths they sell for copper tube, it's easier to make just a 3 el, than larger...But I guess for larger, you could use 2 inch tube for a boom, and use a coupler between pieces to add more length..I'd use the larger 2 inch with more elements, as the boom could sag from the weight..Myself, I'd stick with 3 elements if you used copper...I brazed all the elements direct to the boom. Uses a gamma match made from 3/8 copper tube, and coax innerds "center conductor/dialectric" for a cap..Rg-8 size fits perfect inside the 3/8 copper. There is not much else at Lowes/home depot, etc that will work...I looked when I made mine...The aluminum, and other tubing, angle pieces, etc, they sell are unsuitable. Proper aluminum tube for antennas you would have to find somewhere else. MK

From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <cb37vn$19i$1@sparta.btinternet.com>
Source record: 93215

NOW AVAILABLE ** New Program "BALCHOKE.exe"

This program is very similar to program CHOKEBAL The main change is to input data. The ferrite core is rectangular in shape and defined in terms of thickness and length instead of a circular core diameter. The size of the core is described more conveniently in terms of the outside diameter of the ferrite ring instead of the diameter of the mean magnetic path.

The opportunity has been taken to provide, in the author's opinion, a better statistical way of estimating percent current unbalance in the twin-wire transmission line. There are also better program operating notes.

Although most numerical results are identical this second version of the program is recommended.

Program size about 36 kilobytes. Download program BALCHOKE from website below in a few seconds and run immediately from a desktop icon.

Reg

How can I determine how effective a balun is?? I am working at 137 MHz
and cant consider a radiation pattern range of any kind.
I have been trying a coil of small coax in a relatively low loss ferrite
toroid and then slipping a high permeability tube of more lossy ferrite on
the coax to the receiver. I thought the higher reactance with a reasonable
Q might minimize the current conducted along the feed line. Then, any
currents that do get by the reactive coil might get disipated in the lossy
and high permeability ferrite tube section.

Since I'm working without much knowledge and almost no test equipment, I'd
sure appreciate any information about how to evaluate baluns at VHF.

4264. Re: How to Measure a 2M Yagi Impedance?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-20 07:47:40 UTC
From: Roy Lewallen <w7el@eznec.com>
Message-ID: <10dag909g8itv20@corp.supernews.com>
Source record: 93219

I want to caution you about using a half or one wavelength line to do measurements. That's a viable method if the imedance of the antenna is close to the characteristic of the line. If it's not, you'll find that even a surprisingly small line loss -- one that you'd normally consider negligible, can seriously skew your results. The calculation is straightforward presuming you know the loss -- I'm sure Reg's program would be adequate. Do some what-ifs with various antenna impedances and you'll see what I mean. The effect gets worse as the antenna and transmission line impedances get more different, and as the line gets longer. That is, a one wavelength line will have more effect than a half wavelength one.

Also, line length becomes more and more critical as the impedance of the antenna and transmission line become more different and as the line gets longer. Again, a little experimentation with the calculations will illustrate what to expect.

Even if you carefully account for the transformation of the connecting line or don't use any line at all, you have to be aware of common mode currents and how your test setup differs from your normal rig connection. And finally, even with a perfect lab setup, you'll find that good impedance measurements can be hard to make with amateur equipment.

Before you get carried away, make some measurements on the bench with your meter and using good quality loads, or at least RC combinations using chip resistors and capacitors or ones with extremely short leads. Make impedances similar to ones you hope to measure. If you can get values which are accurate enough to suit you, go to the next step and measure the same loads through a transmission line as has been suggested, and see if you're able to extract the actual load value from the measured value with sufficient accuracy.

If you get that far, you've partially answered your question about what kind of accuracy to expect, and you're ready to start figuring out how to deal with common mode currents.

Decent antenna impedance measurements aren't simple to make, even at HF. They're more difficult at VHF and above.

You've gotten some good suggestions about sources and materials. I haven't seen anyone mention that if you choose aluminum, the stuff you buy at a Lowes-type store is very different than the type normally used for commercial Yagis. It's a lot softer and weaker. I don't have enough experience myself to know if it's good enough for a 6 meter beam, but if so, it'll be nowhere near as strong as something made from the proper variety of aluminum (e.g. 6061-T6) which you can get from some of the sources that have been mentioned. So don't use hardware-store aluminum tubing for anything that requires much strength or durability.

The MFJ 259B will measure the length of the line for you before test.
Leave it open circuited and connect the other end to the MFJ. It finds
the 1/2 wavelength frequency.

> There's no way of proving it exept by climbing a ladder and disconnecting

A bench setup with a 1 wavelength line does not require climbing and
measuring at the tower.

Agree it is a one frequency measurement.

>
> And you have to know exactly what you are doing because the 259B does not

But, the sign of X is very easy to determine. Increase frequency
'slightly' on the 259B and observe absolute value of X. If X increases
it is inductive. If X decreases it is capacitive. BTW the Or is a value
at antenna resonance only at one frequency. But, you a very well aware
of that. The comment is made for other readers.

> ----
> Reg, G4FGQ

There is one possibility remaining. If the Yagi is to be tuned for
MAXIMUM gain, and that is the objective, then Ro will be the lowest
value at resonance. Most Ham yagis are not tuned for optimum gain as we

all know.

There is WAY WAY too much emphasis among today's hams regarding low VSWR. My 75/80 doublet has a VSWR approaching 30:1 and works just FB!! The problem is the absence of output tuning in most of the rigs available today. Oh! for my OLD VIKING II or my Drake 4C. <grin>

Gor Bless and you have my permission to celebrate the USA Father's Day.

Roy, your caution is well placed.

As I've said before, most amateurs and professionals (it seems from these walls) suffer from delusions of accuracy.

Their delusions are seldom frustrated by things going wrong after some tedious, supposedly highly accurate, design work has been done. They congratulate themselves on their success and sometimes follow up by writing learned papers incorporating 6 places of decimals about it.

But in engineering reallity, especially with Radio, things work simply because any bloody thing will work after a fashion. And if the transmitter is loaded with an actual but unknown impedance between 30 and 80 ohms, such that it works, they continue to remain oblivious to their delusions.

I relate this, certainly not to cast ridicule, but with the inention of enhancing the underlying beauty of this intriguing hobby of ours.

Perhaps 'suffer from' are the wrong words.

In the UK it is Father's Day. So I am about to pour myself another glass from a bottle of special reserve port, a thoughtful present from a loving 'doter'.

I have a 6BTV that I'm about to install. It will primarily be used for 80/40/30 meters. Some questions:

I could elevate it, if it would improve performance. The manual says not to ground the radials or the antenna base, so I could mount the unit on an insulated mast, and string the radials at a 45 degree angle....

Or I could place it near the ground, or try a metal mast, or....

Any experience/suggestions?

Gary K5QT

My 2 cents -- my experience with 1/4 wave verticals with ground radials has
been pretty miserable. With many many radials and good ground would probably
be Ok.

When I put the 1/4 wave up on the roof with four radials slightly
drooping -- wow what an improvement.

Also I have had good luck with the Cushcraft end fed antennas with no
radials

Your radiation may vary - hi hi

Source record: 93129

Hello PDRUNEN:

The Hardware Store Aluminum tubing may not last in severe weather and winds. Here in the Mojave Desert we see 90+ MPH winds at times.

Usually 6063 T8 or 6061 T6 Aluminum Tubing is used. The wall thickness used is .058 inches. This will normally allow the Aluminum Tubing to "Telescope" into each other in 1/8 inch increments. Like 1 OD (Outside Diameter)inch .058 will allow 7/8 OD to fit or Telescope inside it.

But be advised wall thickness tolerances sometimes can be thicker NOT allowing the Aluminum Tubing to "Telescope". The Aluminum Tubing Manufactures DO NOT make Aluminum Tubing to "Telescope" unless it is specified by a large order.

The Boom will be the hardest to design and make. Perhaps a older beam boom can be used. If you look around at the different beam antennas you will get the idea. The 6 meter beam shouldn't be a career project. I suggest using split and insulated driven elements, a Hairpin Matching System and a good Balun.

Maybe a local metal supply house can help you out.

Texas Towers sells Aluminum Tubing there at:

http://www.texastowers.com/aluminum.htm

4275. DLM Antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-20 16:21:52 UTC
From: fractenna@aol.com
Message-ID: <20040620122152.04107.00000202@mb-m26.aol.com>
Source record: 93130

Some care must be exercised to see that causality has not been violated: the 'July 9' date is a typo. The right date is, of course, 9 June.

I continue to get many e-mails asking for info about DLM designs. You will, perhaps note, that the 7 June EE times article was AGAIN run--with additions--on 14 June:

http://www.eet.com/showArticle.jhtml?articleID=21600147.

Mr. Vincent describes a design that, apparently, is well within the description I discussed below on 11 June--at least that is my opinion.

As I have not seen Mr. Vincent's design, it would appear that said design is either 'obvious to those skilled in the art', or not novel in some basic way, again, an opinion. I will be most interested to see what true novelty is ascribed and approved as the 'revolution' moves forward.

Incidentally, Mr. Vincent again ascribes his design as "wide in bandwidth" yet describes substantial harmonic suppression. 'Wideband' designs are almost always big enough in passband to cover the lowest end and its harmonics.

73,
Chip N1IR

<<Temat: DLM Antenna
Od: fractenna@aol.com (Fractenna)
Grupa: rec.radio.amateur.antenna
Organizacja: AOL http://www.aol.com
Data: Jun 11 2004 12:29:42

Hello--

I've received about 2 dozen e-mails on this subject. Prior to this, I communicated with Mr. Vincent early on 9 July(SIC) and offered him the opportunity
for scientific and objective independent testing. He declined due to a test already ongoing at a facility that I feel is also capable of such testing (you may ask Mr. Vincent if you wish).

My scientific interest in this topic is exhausted. I pose the following for those interested in what is possible, and what has been done, along the lines of distributed loading of helix monopoles. I invite you to investigate the prior art for yourself.

I have not seen Mr. Vincent's design, but based upon his PR statements, it appears to be a loaded helix monopole with a CCD-like arrangement for neutralization. The design, of course, may be different and novel, although I am not of that opinion, based upon the 3 reports published in the popular press. In the absence of knowledge, it is impossible to fully assess. Still, there is value in knowing what has been done and what is possible.

The prior art is rife with distributed loading of monopoles to extensively shorten them.

Here is a prior art method that will gives a few percent bandwidth and about -2 dBd for less than 1/15 wave height. I invite you to experiment for values and placements:

* Take a half wave of wire (approximately);
* Wind it into a helix of about 10^-3 waves diameter (or less);
* Place an inductive load half way up;
* Add at least 2 and up to 6 capacitors at distributed points along the helix length;
* If you wish to truncate the current at the top, then add a small end cap hat;

Essentially this is a shrunken 1 wave dipole manifest as a 1/2 wave monopole, using CCD (distributed capacitors) to neutralize the inductance. (remember: not all cacapcitors need be discrete components). Helical designs originated with Harold Wheeler more than 50 years ago. CCD articles have predominantly appeared in ham magazines in the 70's and 80's, although the original invention is (I believe) British and over 40 years old. There are many relevant patents, all expired to my knowledge.

This design approach will 'linearize' the current (slow he wave) and do a pretty good job. A shrunken 1/2 wave monopole does better than a shrunken 1/4 monopole. When you compare it to a full-sized 1/4 wave monopole it will do well at a specific frequency.

It is an interesting question whether the relevant comparison should be to a 1/4 wave monopole or a 1/2 wave monopole. Such shrunken designs are 1/2 wave equivalents, not 1/4 wave equivalents. They will look much worse in performance compared to full sized counterparts. A 1/4 wave monopole is not a counterpart, although in a practical sense it is a much used antenna which one might seek to replace and thus compare to.

HOWEVER for such a shrunken design--

* It will be moderate to narrow band;
* It will trade gain for efficiency and is NOT efficient;
* It will run hot in continuous-on applications with moderate to high power.

Gain is not efficiency. Sometimes efficiency doesn't matter, but gain does. Other times the heating from inefficiency will kill an otherwise elegant design option.

Mr. Vincent's original PR claims, to my recollection: high efficiency; good (broad) bandwidth; very low height.

These are not mutually, physically, attainable. I, and many others, have spent enough time to know. There is no reason to believe that Mr. Vincent has attained these. What he has appeared to have attained, to my limited knowledge based on published PR, is: moderate to low efficiency; modest bandwidth, and very low height. To my knowledge, Mr. Vincent has neither done an efficiency test nor a heating test.

In terms of applications, there are very few, besides some 'ham' and CB needs, where a single band, somewhat inefficient whip is desired. Midland has a nice compromise stick for CB'ers that's using some of these ideas and is two feet high. I like their design.

--Using a heavily shortened CCD type helix monopole in a broadcast app will lead to a fire. It is not highly efficient and the wasted power will manifest as heat. As little as 30 watts of heat in a confined area will start a fire or melt components if not properly dissipated. About a 1 dB loss to heat for 1000 watts power will produce well over 100 watts dissipated heat. Ergo, even a reasonably efficient antenna is potentially dangerous if high power is used and the heat is not properly dissipated. Mr. Vincent's design PR describes melted components in some of his design efforts. This indicates inefficiency in the design tested.

--Much of the world wants 'ground independent' antennas--not monopoles

-- Microwave applications are not single frequency, with few exceptions. Even PIFA (inverted F) solutions--which are extremely low height, lower than Mr Vincen'ts-- are multibanded.

--Much of the world wants multiband antennas, or wideband antennas, not modest passbands.

==========

It all depends on what YOU mean by "effectiveness".

First ask yourself why, in your case, you think you need a balun.

If you are referring to common-mode current on the feedline then you have to state your requirements in numerical terms and find some means of measuring it as a fraction of the total line current, without disturbing the antennas normal environment.

But that's only half the job. Assuming you have some objections to common mode current you then have to numerically relate common mode current to the adverse effects it may have on ALL other aspects of antenna performance. And unless you have some idea of the MAGNITUDE of side effects you don't want, you can't sensibly talk about it.

Just a caution, nobody ever talks sensibly about power being radiated specifically from feedlines. There's no such stuff. ;o)

The best way I can think of of discovering what a balun is actually doing is to entirely remove it from the antenna and see what happens to antenna performance in terms of the all-important radiation pattern and gain. If within your limited means of measurement you can detect very little or no difference then, of course, don't bother to replace it. The usefulness of baluns is often overated.

Similarly with your ferrite coil and tube experiments. If by doing something, nothing happens, then don't do it.

Praps you could make a very simple current detector (a current transformer) which will fit around the feedline. A pair of suitably-shaped ferrite blocks plus a few turns of wire plus a diode plus a 500pF capacitor plus a 100-ohm resistor plus a DC microammeter are all that's needed.

But making measurements at 137 MHz is fraught with error even by experts.

If your antenna is for receiving purposes only, then its 99.9 percent certain you don't need a balun anyway. And a few turns of a few inches of small diameter coax on a small ferrite ring can't possibly do any harm even if you decide to use one. It is sure to work as intended even if you've no idea how well it's supposed to work.

Reg.

Yep this has been around a long time. Got one in my junk bin made of
coathangers and N connector for two meters> It worked so much better than my
rubber duckie antenna I thought it was the greatest antena in the world..

Hello fellow shortwave listeners !

More info to make a T2FD yourself, like I did mine, please have a look at:

http://members.home.nl/rita.kees/t2fdmake.html

I hope you can appreciate it and use it for your practice.

I will be glad to answer your questions.

73/cheers

Kees

4281. Gamma match question 6-meter yagi

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-20 19:13:09 UTC
From: Shadow 998 <hrd998cc@nospam.yahoo.com>
Message-ID: <9llBc.2590$7i7.1795@newssvr25.news.prodigy.com>
Source record: 93136

I am tuning up my homebrew 6-meter yagi and find that the rod inserted into the capacitor tube of the gamma match is only inserted by about 1-1/2" to obtain 1:1 SWR. I guesstimated and cut the spacer and shorting bar for the match to provide about 1-1/2" parallel space between the gamma match and the driven element. I did this because the text of the article did not specify the space. Is this dimension critical? Is it normal for a 13" gamma match to only need 1-1/2" of rod insertion to obtain the proper capacitance?

Thanks.

if its working then thats where it should be.

gamma match design and tuning includes:
1. distance of shorting bar from center of element
2. space between gamma rod and element
3. diameters of gamma rod and element
4. capacitance added at feed point
5. length of the whole driven element

all 5 factors go into the final match. some are easily changed, like the capacitance, shorting bar location, and element length. the others are harder and are usually selected to get in the ballpark and then the easy ones are adjusted to get the desired match.

Reg

The only thing I have been concerned about is the radiation pattern. I have been trying to "disassociate" the coax's outer conductor with a dipole so the radiation pattern will be essentially that of the dipole.

I have been trying to think of ways to make impedance measurements so I might be able to estimate the reactance to currents cunducted along the outside of the coax.

I really appreciate your comments on the practicallity of winding a few turns of small coax in a small ferite.. That seems to have provided the best insertion loss I've been able to acheive.

I've been trying to make a simple antenna for receiving NOAA satellites. I have been learning that my antenna concept is of limited value for producing clear pictures from weather satellites. But, I still want to get more data on antennas so I might be able to get better pictures from a "simple" antenna.
My principal problem right now is minimizing the nulls in the pattern. Each null will produce a black line in the picture of te Earth when that null falls below some threshold.

Thanks again
Jerry

Hi Russ,

It seems I ran across a short hand for the required capacitance for
the common gamma match that offered somewhere between 2pF and 5pf
times the wavelength of the band. That is, 12pF to 30pF - not much
especially if the rod is a close fit with a small dielectric layer.

==========

Fine on your comments Bill except for the oft-repeated number of 120 which must have been originated by Marzipan the Magician. It is far too extravagant.

For amateur purposes 32 radials are 'enough'. And that only because it's twice 16, which is twice 8 - - - - down to 2 which is twice 1.

Over a wide range of soil resistivities and radial lengths, the electrode-to-ground resistance of 32 radials is only about 1.3 times that of a solid copper disk of the same radius laid flat on the ground.

The electrode-to-ground resistance of 1 radial is about 6 or 7 times that of 32 radials so unless immersed in salt water it may be well worth while increasing to 4, 8, 16 or even 32.

In average soils and with radial lengths of around 20 metres, the electrode resistance of 32 radials will already be as low as 3 ohms which is perfectly good enough for less than a 1/4-wave or 5/8-wave vertical and far better than necessary for a 1/2-wave vertical. To increase to 120 or more radials is just a waste of good copper plus a lot of hard labour.

The following table is for a typical ground resistivity = 200 ohm-meters (conductivity = 5 milli-Siemens), radial length = 66 feet, wire diameter = 14 awg, buried depth = 1 inch.

Radials	ohms
1	24.6
2	13.6
4	8.0
8	5.3
16	4.2

32 3.3
64 2.8
128 2.7
Disk 2.5

For a 1/4-wave vertical I wouldn't bother with more than 16 radials with which efficiency is of the order of 90 percent. Or an undetectable 1/12 of an S-unit less than perfection.

If ground resistivity is not known, as it nearly always isn't, then a logical way to proceed is to keep doubling up the number of radials until the received signal strength of not too distant stable transmissions stops increasing. Then add 2 or 3 more for luck. But I doubt whether the new magic number of 32 will be exceeded.

Regarding length of radials. The propagation velocity along wires buried in the ground is very much smaller than in free space. When lying on the surface of the ground it about half the free space value. So surface radials need never be longer than 1/8 wavelengths.

Furthermore, the loss along buried wires is very high. Of the order of 8 dB per 1/4-wavelength at their own velocity. So there's little point in having buried wires much longer than 10 meters or 33 feet on the 160m band, and progressively shorter lengths at higher frequencies. At distances where there's no current flowing in the wires there's no point in them being there. Nobody uses ground radials for 15 and 10 meters anyway.

Do I hear anybody shouting "Heretic" ? ;o)

Reg, G4FGQ.

Hi Jerry,

I noted the dearth of numbers that necessarily informs the
discussion....

Achieving those numbers is a relatively simple task one can perform
from the safety of an arm chair. You simply observe that the
prospective antenna exhibits some Z. This is usually known to within
ï¿½100%. As it is often designed for coaxial feed, a valuation of 50
Ohms is easily within any variation of actual value.

Now, the exterior, offending radiator of the coaxial shield is an
unknown. However, there are a range of possibilities that are hardly
tasking of the mind to anticipate. Certainly that alternate path will
represent no load less than 50 Ohms impedance for your band (the
antenna isn't fractions of a wavelength away from your transceiver is
it?). However, let's give that the benefit of the doubt as that would
be very disruptive.

To snub that second 50 Ohm radiator (or less), you should add at least
3 times the antenna Z, preferably 5 times, and conservatively 10 times
to the common mode path. One bead (that will snuggly fit RG-58)
suitably chosen would offer 20 of those Ohms, if not more to that
common mode path when the coax is slipped through it. I will leave it
as a simple task to compute how many beads (no unzipped software
required, no download, no immediate running to wait for).

If on the other hand that exterior braid offered some multiple of
halfwave, it would exhibit an exceedingly high Z such that no snubbing
at all is required as that value would presumably eclipse the
requirement. Those that doubt may now retire to the bench to confirm
or deny. To be blunt, this is simply a fork in the road situation
(parallel loads for those who demand a technical discussion), you are
adding barriers to the less preferred path.

However, from the comfort of that same arm chair, it may be simply
argued that this exterior dimension offers every prospect of being
either unknown, or variable over the life of the installation (unknown
in some futurity). The resolution of that argument is to build the
choke and get on with life by getting out of the arm chair only once

to install it, and thus anticipate and resolve all unknowns.

Not all solutions require software, nor incantations of the mystery of the flux density. ;-)

4288. Re: How to Measure a 2M Yagi Impedance?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-20 21:40:38 UTC
From: Dave Shrader <david.shrader@comcast.net>
Message-ID: <qvnBc.66450$Hg2.43822@attbi_s04>
Source record: 93143

I've been away from Yagis for many years. But, maximum gain requires maximum radiation which requires maximum current which requires lowest radiation resistance. Twenty years ago, or so, Ro of 15 to 20 ohms was common in high gain Yagis wher Gamma matching was used to raise the impedance to approximately 50 ohms. A slight reduction in gain allows Ro of close to 50 ohms.

Kraus, Antennas, McGraw-Hill 1950, Chapter 11 provides the analysis for a simple 2 element 'Yagi' type array. In written terms, the driving point, feed point, resistance, ignoring losses, is the radiation resistance of the driven element minus the ratio of the mutual impedance to the self impedance of the parasitic elements. Far field gain is maximized by a term where the input power is divided by the net impedance of the driven element minus the net impedance contributed by the parasitic elements.

Conclusion, maximum gain, in any configuration [3 element, 4 element, etc.], requires lowest Rr produced by highest mutual coupling.

I'm not arguing that more gain is produced by the longest boom or the most elements. What I am stating is that for any configuration the gain for that configuration is MAXIMIZED when the Rr is minimized.

Richard

I had never even cnsidered that there is a practical amount of impedance
that the balun neds to provide. Thats a good thought for me to use.

I have been picking up parts to build a slotted line. And now I see that
I might be able to build an impedance measuring device per VK2KU and VK2ZAB
information. I plan to go to some nearby surplus stores tomorrow to look
for parts for an impedance meter. It is likely that I'll learn more about
building test equipment than I learn about the antennas I trying to
understand.

Even if this effort to try to build a simple antenna fails, I am enjoying
learning about stuff I like to be informed about.

Thanks
Jerry

Hi Jerry,

The road less traveled here in this group (to the bench) will confirm
your anticipated stages of the cross. ;-)

I have constructed a binary variable length transmission line from
precision coaxial components (Cecil once tried to argue its
characteristic Z was 40 Ohms to deflect a thread) found at this
source:
http://www.microcoax.com/semirigid/intro.htm

I don't know how deep your pockets are for this effort, but it will
let you know that precision and accuracy are available.

Richard and Dave, Thanks for the quick responses. It sounds like it is OK as-is. Using a borrowed MFJ analyzer, I was able to get the SWR literally flat at 51.9Mhz. The bandwidth is pretty good too: 1.2 @ 50Mhz and maxes out at 1.7 @ 54Mhz. All in all, I'm quite happy so far.

This is my first attempt at 6 meters and have not made a single contact on the band since getting my license last year. This year will also be my first field day which is why I built this beam. Now to figure out if it has a F/B ratio, forward gain, etc.

Again, Thanks for the help.

Hi Russ,

You might want to consider if your lack of contacts is due to being
cross polarized with those who you wish to work (or be heard by) - or
using the wrong mode.

Jerry,

Let me say at the outset, whether you use a balun or not, there will be no detectable effect on the radiation/receiving pattern of the antenna. For practical purposes it will remain the same as the usual radiation pattern for a half wave dipole.

You appear to have a 137 MHz 1/2-wave dipole fed via a coaxial line. Ideally it should be a 75 ohm line and to prevent reflections from the receiver end it should be terminated at the receiver with 75 ohms. But if reflections don't matter with whatever type of signals you wish to receive then a 50-ohm line can be used. But neither impedance will have any effect on the antenna's radiation pattern.

I can talk in terms of radiation pattern because the receiving and radiation patterns are always identical for either transmitting or receiving purposes. This results from the effect known as "Reciprocity".

When transmitted or received currents appear on the outer coaxial conductor of the feedline they are known as "common-mode" currents which cause the antenna and feedline to behave as one single, differently shaped antenna. The radiation pattern of the differently-shaped antenna results in distortion of the original dipole's pattern.

BUT WHAT MATTERS IS THE MAGNITUDE OF THE CURRENT WHICH FLOWS ON THE OUTSIDE OF THE COAX COMPARED WITH THE MAGNITUDE OF THE CURRENT IN THE DIPOLE.

The common mode current in the coax flows along the whole of its uncertain length and so affects the radiation pattern in an uncertain manner. Furthermore the unknown impedance to ground at the receiver end of the coax obviously has an effect. The whole business is indeterminate and can be treated only in a statistical worst and best case manner.

Available from my website is program FEEDPOWR program which deals with the transmitting case and attempts to estimate the power radiated from the feedline relative to the power from the dipole antenna proper, versus dipole length, feedline length and frequency, taking the resistance of the ground connection at the end of the coax into account. It does not take into account that the lower part of the feedline, perhaps inside a building, does not radiate at all well and so the program very nicely over-estimates the unwanted effects.

If we examine your particular case by entering in the program a dipole length of 1.09 metres, a frequency of 137 MHz, a feedline length of whatever you've got, and a ground resistance of 50 ohms for the want of a better value, we find that that the worst case value of power radiated from the feedline is about 6 percent of the total transmitter power as line length is varied. The best case value is about 1 percent as line length is varied.

The change in shape of the radiation pattern is at worst of the order of 0.4 dB which I suggest is negligible and undetectable. It is less than that due to not bringing the feedline away from the dipole at an angle of 90 degrees for the whole of its length which can also affect the radiation pattern. Nearby buildings, phone and power lines, can also affect the radiation pattern of an ordinary dipole and almost certainly will.

Due to reciprocity the effect on the receiving pattern will be identical.

As I said earlier you don't need a balun. But if you are a perfectionist no harm will be done by fitting one. You will obtain no useful information by attempting to make measurements of any sort. A ferrite choke balun is so simple there's nothing to go wrong with it. Keep the length of small-bore coax wound on the balun to less than 1/15 wavelengths. Just a few turns on a 1" diameter ring.

Thanks Roy,
But for those equations to be valid circular represenations,
don't Eh & Ev need to be equal? As they stand, substituting "random"
values for Eh & Ev will yield elliptically polarized waves.

Your best bet is to listen from about 50.100 to 50.200 on SSB. Calling
frequency is 50.125. East cost was working the West coast earlier today. I
assume the beam is horizontally polarized. Good luck on 6.

I think I have identified the beam. It appears to be a Mosley CL
33-M-WARC. I was wondering if someone might have the manual of this
antenna. I would love a scanned copy, but I would be willing to pay
for a photo copy. Thanks for your help!
It has an interesting feed design. It has two small aluminum tubes to
each driven element and is fed at the center of each small tube in the
center. I'm wondering if one driven element is for the conventional
10-15-20 beam and the other is 12 and 17 dipole? Any help would be
appreciated!

Yes, quite interesting, since a yagi is _not_ resonant in the design
frequency range, otherwise it couldn't work.

No.

All waves are elliptically polarized. Linear and circular are two special cases of eliptically polarized waves. For analytical and computational convenience, you can split any (elliptically polarized, TEM) waves into two orthogonal components. One choice of two components is vertical and horizontal linear. Another, equally valid, choice is left and right circular. You can convert between one and the other with the equations I provided.

To be purely linearly polarized, Eh and Ev have to be in phase or 180 degrees out of phase. To be purely circular, Eh and Ev have to be equal in magnitude, AND in phase quadrature. There is no combination of Eh and Ev except both zero which result in the left or right circular components to be zero. That is, a purely linearly polarized wave can still be split into left and right circular components, and neither of those components will be zero unless the field itself is zero. Likewise, a purely circularly polarized field can be split into non-zero vertical and horizontal linear components.

My, we can sure learn a lot of new things about Yagis from this newsgroup. Unfortunately, they're not true.

I have a very high confidence in the ability of EZNEC to accurately model Yagi antennas. This is due to feedback from several professional customers who have analyzed Yagis with EZNEC and tested the actual antennas on test ranges.

Let's take the EZNEC example file NBSYagi.EZ.

If you change the driven element (wire 2) length from 2 * 54.875" to 2 * 54.56", you'll find that the feedpoint impedance is 11.53 - j0.0752 ohms -- it's resonant, and it's certainly functioning as a Yagi. The pattern and gain are nearly identical to the original NBS design.

Now, change the director (wire 3) length from 2 * 54.313" to 2 * 56". This drops the gain from 9.68 dBi to 8.66 dBi, and lowers the feedpoint resistance from 11.53 ohms to 7.849 ohms. The point of maximum gain is obviously not the point of minimum feedpoint resistance.

Anyone having an explanation for why the gain should be greatest when the feedpoint resistance is minimum and why a Yagi can't work when resonant should examine their explanations carefully in order to uncover the flaws that are obviously present in the explanations.

I found that my garage is WAY to far away to use this setup.

Following the formula, I took an average frequency of 10 Megahertz. I divided into 100, as per the formula. I got an antenna length of (100ft/10,000,000) = 1 X 10^-5 feet, or 0.00012 inches.

I then thought that this just couldn't be right. I redid it using Meters instead of feet and arrived at 0.00001 meters length. MUCH BETTER! The problem now is that the store only sells full length rolls of wire. Where can I mail order a smaller chunk? Can they just wrap the postage stamp around it to save shipping costs?

Being ever on the watch for cheap alternatives, what is a cheap way of relocating the far end antenna support?

I don't want to pay to have the garage moved.

Any insights appreciated.

mike

Center-fed dipole-based antennas don't need station or installation
site RF grounds. Horizontally or vertically oriented. All end (base)
fed verticals need RF gounds so don't use 'em in your situation.
Safety gounding which is not RF grounding involves, in the limit,
tossing the feedlines out the window and ducking when boomers pass
thru the neighboorhood.

The Tilted Terminated Folded Dipole ("T2FD") is a broadband folded dipole
antenna design that provides a relatively
stable feed point impedance over about a five to one frequency range. The
antenna
length in meters is approximately 100 divided by the lowest desired
operating
frequency in megahertz. The upper element of the folded dipole is opened in
the
center and a non-inductive terminating resistor of around 350-400 ohms is
inserted.
The bottom element is fed in the center through a 6-to-1 balun for a good
match to
50 ohm feed line.

The antenna is not as efficient as a matched half wave dipole at any
specific
frequency, but it also does not require an antenna tuner for operation,
making it
easy to use. The loss of receiving efficiency is not generally noticeable
in the high frequency range (2-30 MHz), amounting to less than 6 db (one
standard
S-unit) during extensive on-the-air testing.

Here is additional information on the T2FD antenna.

Barker & Williamson actually applied for a US patent (US Patent #4423423)
for their specific T2FD antenna design.
http://www.fact-index.com/t/t2/t2fd_antenna.html

While this may be acceptable for SWL operation, the resistor does not have
sufficient wattage for
any station attempting to use this for a transmitting antenna.

I want to build a nice small antenna for my boat. I had a J pole in a PVC tube, but I thought about a vertical dipole of the sleeve type. Can you make such a beast with the coax and just remove outer insulation and then pull braid back over the coax until they are both the same length? I want it for 156.8 MHz so it should be around 1.5 ft per side. But I have seen an article that says the top portion should be smaller than the lower braid portion to balance things out electrically. Can anyone shed some light on this for me? I have tried it and my analyzer doesn't show it resonant anywhere near that freq. Hmmmm.
Help please.
Any other good marine antennas that are easy to build would be great if you have plans or ideas. Thanks folks.

Reg

I see there's something wrong with the way I'm looking at radiators. I have been thinking that the currents conducted on the outside of the coax feeding a dipole would noticable effect the dipole's radiation pattern. I've been thinking that when coax is used to feed a balanced dipole, half of the dipole thats connected to the center conductor will see a V shaped dipole half thats composed oof the other half of the balanced dipole *and* the outside of the coax. Maybe this above sentance is not conveying the message. But, do you see where I'm making my mistake??

If I interpreted the manual correctly, it indicates one should insulate the antenna base from a pole or tower that is nearing 1/4 wavelength. It didn't seem to caution against conventional mounting if the tower or support pole was a different length....

The manual seems to provide reasonable information regarding the use of radials at 45 degree droop, recommending their use if possible. Ground mounting is generally noted as being less desirable than roof or elevated mount with 45 degree radials...

I have a 5BTV and the antenna on the higher bands (10, 15, 20, 40) has reasonable bandwidth, but on 75 meters the bandwidth is extremely narrow, do much so it is nearly useless unless you have a single frequency you normally use... Sitting on the ground, using two radials per band provides acceptable performance on 10-40m, but on 80, it took 4 radials to get the swr down to 1.5:1, and even then, the bandwidth between the 2.0 swr points is only about 60 khz at best. You really need to pick your operating frequency for 80m. In a few weeks I'm going to try to roof mount it to see if I can get a wider bandwidth on 80m.

Good Luck!

Hi Jerry,

I presume we are proceeding from your design toward its validation of characteristics specific to the purpose of monitoring satellite signals. I further presume chief among these characteristics is near omnidirectionality with an even gain distribution. Of course these presumptions may be wrong or incomplete (I may have neglected issues of circular polarization). Anyway, as an example I have offered:
http://www.qsl.net/kb7qhc/antenna/Inverted%20F/index.htm

If this example suggests some similar quality, then your design (if it exhibits less than uniform characteristics) would stand to gain by any additional sensitivity that comes by way of an excited common mode which fills a null. Problem is, this means the total absence of choking, which returns us to the vagaries of luck which will not always offer such generosity.

Thus the virtue of choking is to guarantee an independence from caprice doing your designing for you. You are then responsible for doing it your self at the antenna and the choke makes it independent of the feed line. The alternative is to find the perfect combination

of line length and antenna (observing only those beneficial orientations between the two) and imposing that upon your user to meet the design requirements.

A very loaded question..

Best in what way?

Loss is usually a function of diameter, frequency and dialectric.. and
of course the loss is a linear function with cable length... If that is
what you are after then you have to work out how much you can afford to
lose vs the cost of getting more expensive cable and connectors. Between
"good" brands you will find that there isnt much difference in loss...
The "bad" ones (often cheap) will have a centre conductor that wanders
and imperfect shield weaving.

Quality as in how long it will last in the sun?

In our commercial installs we use Andrew and Belden. Note that I am
talking about coax that is rarely less than 1/2" in diameter. Beyond
water ingress from badly terminated connectors and direct lightening
strikes we are more than happy with them.

Mr Cebik has a goodly array of antenna designs.
(http://www.cebik.com/radio.html) No doubt you could scale a 900Mhz one
or make something a little wide band like an LPDA or corner reflector.
Google also returns a plethora of make yourself 900MHz antennas.

Cheers Bob VK2YQA

My local "Do It Center" hardware store has started carrying 6 foot lengths of T6061 aluminum tubing in 1/16 inch diameter increments up to about 3/4". For general experimentation and short elements, those might work out for you. For more serious work you should probably order from a place like Texas Towers.

I can't tell you where to buy, but can tell you my experience with their
VHf/UHF model.
When I received it I found out that the software does not control this model
as it does the HF- it simply allowed plotting. Nowhere was this revealed in
their literature. I used my set of Hewlett Packard precision terminations to
check the AEA calibration. On VHF, best return loss (VSWR) was at 62.5 Ohms.
On UHF it was 75 OHms. When I called AEA to ask about this, I was told "that
is about what you should expect from a $500 instrument. I sold it at the
next hamfest and bought an Autek unit.

I tried a couple on my Yaesu VX-5. Didn't do any really definitive testing
but subjective ability to access repeaters or other Hams in this rural area
wasn't noticably improved - at least not enough to warrant the bother, so
I'm back to the stock antenna. Naturally, others may find the opposite, but
I'd say "Save your money".

<< On the rs
meter I am reading infinity for swr at roughly 30 watts on cw (really only mode I use) on 40 meters. On the scout meter, I am reading at most, 2:0. Now the scout has an adjustment on the bottom for power. With the radio on, into a dummy load, as I increase wattage, swr goes up and the ALC light goes out. >>

Hmmm...using the old "50% efficient" rule of thumb gives around a 5 amp draw at 30W out. Think the first thing I'd do is read the manual to see what the current needs are...replace the RS meter with a decent one (the RS meter will work, but not a "good" meter) and get a decent (Astron, etc) power supply in the 12A and up range (I recommend the RS20 or RS35...good units).

Greg, one thing you may be able to do immediately is to get a gelcell of some sort and trickle charge it...I use a 17aH cell to run my FT857 at 50W (w/solar charger). What you are seeing, in part, is current limiting and loss of regulation on the power supply. The antenna matcher probably is fine, the RS meter will give a fair indication of what's going on. On the power supply side, you may want to review some of the ARRL handbooks which cover P/S information. This will give you a good start in understanding the amount of current needed for a particular application. The fine folks at Ten Tec can provide the manual (which may also be online somewhere for download).

Watch out as regards Polarity....tough to get the smoke back in those little black cases.....

Hope this helps!
A

Rick,
I suspect that '60 Khz' was a slip of the typing
fingers, 'cuz that ain't bad for a 5btv on 80 meters.
Most commercial vertical antennas that cover 80 meters
(and some on 40 meters) have a very narrow range. The
5BTV is no exception...

>and horizontal linear components.
>
>Roy Lewallen, W7EL

Sooo,
we can say that "slanted" 45 deg (circular) polarization as produced with full wave square shaped quad loop fed in a corner has vertical and horizontal components that are (typically) 3 dB down from the maximum in 45 deg plane?
According to modeling software, which shows vertical and horizontal components of slanted polarization, the radiation pattern is a composite of both, with antenna responding to either V or H polarized waves (with 3 dB down from slanted) and according to pattern "belonging" to each (V or H) polarization. Is anything wrong with this statement?
Can we then say that "slanted" polarization antenna has practically "dual" (V and H) polarization properties with 3 dB down from slanted orientation?
Advantage being fuller radiation pattern (minimized nulls) and polarization "diversity" at a cost of 3 dB from the "ideal" slanted orientation.
One "Guru" on his web page claims that there is no such thing as dual polarization.
The "problem" seems to be in semantics. I see nothing wrong calling it "dual" polarization, because it produces combination patterns "belonging" to either V or H polarized antennas, (with 3 dB down from ideal slanted) and fuller pattern than either of V or H alone.
It ain't so, am I wrong?

Of course. Sorry about my retrograde calculations, however, the numbers provided on the site need to be clarified, as they don't work either in either method.

An example at the bottom of the page using the proper units would be in order. The confusion is what caused me to post to begin with.

100 anything divided by millions of other units is bound to cause very small numbers and in this case very small numbers give birds no place to perch.

Tam,

Yes, the beam is horizontal, and I finally made two contacts on 50.155 USB shortly after my last post. I hooked up with two stations; one was about 40 miles away feet on a mountain (he came in @+20 over), the other roughly 80 miles (right in with the noise). Since my antenna is only 8-9 feet above the ground, it's encouraging.

The F/B ratio seems ok.

Thanks for the response.

Richard

Obviously, you have the right idea about what I'm trying to do. And I
realize that I'm trying to build something that I am not actually able to
analyze.
I'm top posting because I have nothing valuable to add to the information
you have offered below. But, I do have to admit that I've become such a
poor learner that I havent yet been able to visualize what that antenna
looks like. It sure has the right kind of pattern.
I may be wrong about what kind of pattern is preferable for polar orbiting
satellites. But, it seems that good right hand circular polarization is
desireable toward the horizon, and can be linear when the satellite is at
higher angles.

You're confusing 45 degree linear polarization with circular polarization. Even though both have equal horizontal and vertical components, they're not the same. The difference is that in a linearly polarized wave, Eh and Ev are in phase. In a circularly polarized wave, they're in phase quadrature (90 degrees out of phase with each other). That makes a large difference. Other relative phase angles result in elliptical polarization with differing axial ratios. In a purely linearly polarized wave, the amplitude of the field goes from zero to maximum, back to zero and maximum again, and back to zero each cycle, and its physical direction of polarization stays constant. In a circularly polarized wave, the magnitude of the field stays constant, but its physical direction of polarization rotates through a full circle each cycle.

> anything wrong with this statement?

No.

> Can we then say that "slanted" polarization antenna has practically "dual" (V
> and H) polarization properties with 3 dB down from slanted orientation?

Yes.

> Advantage being fuller radiation pattern (minimized nulls) and polarization
> "diversity" at a cost of 3 dB from the "ideal" slanted orientation.

The "fuller" radiation pattern doesn't necessarily follow. And it still suffers the disadvantage that a linearly polarized antenna whose polarization is slanted the opposite way (at right angles to the wave

polarization slant) will encounter much more than 3 dB attenuation.
That's why circular, rather than slanted linear, polarization is often
used for FM broadcasting.

> One "Guru" on his web page claims that there is no such thing as dual
> polarization.

Please re-read what I said in my original posting. We're describing a
single wave by mathematically dividing the field into two orthogonal
components, which we can call "polarizations". We can choose horizontal
and vertical linear, left and right circular, or an infinite number of
other combinations, including right-slant, left-slant. A wave has only
one E field; our description of polarizations is one of convenience. If
I choose left-slant and right-slant, I can declare with complete
accuracy that your wave has a single polarization component. If I choose
instead vertical and horizontal, I find that it has two equal
components. If I choose some other combination, I find it has two
unequal components. All are equally valid descriptions of the single field.

> The "problem" seems to be in semantics. I see nothing wrong calling it "dual"
> polarization, because it produces combination patterns "belonging" to either V
> or H polarized antennas, (with 3 dB down from ideal slanted) and fuller pattern
> than either of V or H alone.

Suit yourself. Arguing about it would surely be good for at least a
couple of hundred postings, providing an extended diversion for the
entertainment challenged.

> It ain't so, am I wrong?

No, you're right. It's dual polarization. And you're also wrong, since
it's also single polarization (left-slant or right-slant linear).

People with a deep interest in this topic might benefit from the new
EZNEC+ program type, which can display the field strength from any
antenna in terms of left and right circular as well as vertical and
horizontal linear components.

You did the hard part. Since the antenna is about 1/2 wavelength up, it
should work like gangbuster on 1000 - 1500 mile paths when the band is open.
Oddly, I have worked at least two W0s from here in NJ whose antennas were
strapped to the side of a pickup truck. The 80 mile path will work a lot
better if you can get it about 30 feet up.

Think of the coaxial line formed by the pulled-back braid (outer conductor), the vinyl jacket (the dielectric), and the braid of the feedline going up (the inner conductor). It's shorted at the top end, and you want it to be 1/4 wave long so it reflects an open circuit at the bottom where the feedline emerges. But that's 1/4 wave considering the velocity factor of that line. And the vinyl jacket has a fairly high dielectric constant, so the VF in that section may be about 0.5. If you cut it for 1/4 wave in freespace, that makes it close to 1/2 wave considering the VF. That's really bad: it reflects a short instead of an open, and there's no decoupling between the antenna and the feedline. If you want to do it right, use a tube for that sleeve whose ID is a few times the diameter of the coax feedline, and it would be ideal if you remove the jacket and just have a very few thin dielectric "washers" to keep the feedline centered in the sleeve tube. Then it's tough to mount! So another way is to make a rigid feedline (like from copper pipe), maybe 40 inches long, with a rigid sleeve (which of course is the lower half of the dipole, too) over it and then you can mount it by the rigid section of feedline. At about this point, isn't it easier and more reliable (potential serious safety issue here for a boat, eh?) to just buy a commercial antenna?

Cheers,
Tom

Tom,
I never tried this, but always wondered about using a 1/4 wave section of
triaxial transmission line, Should be able to get the length right with an
MFJ 259/269. Another idea would be a piece of 1/2 inch ID copper braid.

W9GB,

B&W makes two general statements about the T2FD:

* For example, an {T2FD} Antenna for the lower portion of
Shortwave (3 - 18 MHz) will be roughly 33m (110 feet) long,
with conductors spaced 1m (3.3 feet).
[With a Top End mounted about 60 Feet High at 30 Degrees.]

* In order to cover the higher portion of Shortwave (5 - 30 MHz),
this {T2FD} Antenna will be roughly 20m (66 feet) long,
with a spacing of 60 cm (24 inches).
[With a Top End mounted about 40 Feet High at 30 Degrees.]

Build one size or the other = No Formula Required.

Source record: 93094
Cross-posted to:
rec.radio.amateur.antenna,rec.radio.amateur,rec.radio.amateur.digital,rec.radio.amateur.digital.misc,rec.radio.amateur.dx

I just submitted the FCC comment below (in case it provides
any useful ideas to other potential comment submitters).
I'm planning to follow up with letters or emails to my
congressional and senate representatives, per the ARRL
pages.

"This comment addresses the proposed deployment of BPL
(Broadband over Power Line) systems.

As a career radio frequency design engineer, it is obvious
to me that widespread BPL deployment would cause massive
degradation of most licensed radio services now operating in
the HF (High Frequency) spectrum-and some services would
be completely destroyed in the U.S.A.

This expectation follows directly from the fact that power
lines at HF frequencies are poor transmission lines, but are
quite efficient antennas. BPL lines will therefore radiate mas-
sive interference levels (by HF standards), and will themselves
be vulnerable to interference from licensed HF transmitters.
I am confident that my expectation in this matter is basically
the same as any other qualified engineer who considers BPL
objectively.

There is abundant evidence of the expected interference
problems in BPL field trials around the world. And there
are no examples that I know of where BPL is successfully
coexisting with licensed, co-located HF radio services.
For these reasons, BPL has already been rejected by a number
of "HF aware" countries.

The HF radio spectrum is an extremely valuable natural resource
with the unique ability to provide direct, world-wide wireless
communication. It would be highly irresponsible to allow the
destruction of this unique resource simply to provide a redundant
and probably unreliable option for internet connections.

I urge the FCC to do the following:

(1) Provide rigorous protection for the licensed radio
services now operating in the HF radio spectrum
from unlicensed emitters like BPL-both through
appropriate rules and through vigorous enforcement.

(2) Insist on thorough, objective, and successful field
trials-designed to scrutinize interference potential-
BEFORE allowing the widespread deployment of any BPL
system.

Sincerely,

<signed>"

GO FOR IT, and good luck!!!

The fact that we get widely varying reports about the performance of the T2FD antenna suggests that an equally-long dipole would give good results across the frequency spectrum if used with an antenna tuner. What the T2FD really buys you is the ability to avoid an antenna tuner.

There is an amateur antenna out there consisting of an 80-meter dipole (I mean one that is a half wave at 80 meters, not one physically 80 meters long) fed with about 100 feet of 450 ohm ladder line. It turns out that 100 feet of line is within about 10% of the idea length to match the antenna to 50 ohms on all amateur bands. One design of this antenna uses a tuner to correct for the mismatch, while another uses various lengths of 450 ohm line added to the feedline to achieve a match.

I have no idea how well the antenna works, but the method of connecting the
reisistor is very complicated. May I suggest:

Connect the two wires to a normal dog-bone insulator, and solder the
resistor across the insulator to the two wires. Insulate if you wish. For
receive only, a 1/2 W resistor is as good, or better.

QSL, I plead guilty to confusion and oversimplification, I really meant
"slanted linear" polarization.

>No, you're right. It's dual polarization. And you're also wrong, since
>it's also single polarization (left-slant or right-slant linear).

Well (as belowed Ronnie would say), I feel more right in the quest for design
of antennas that minimize the polarization fading and cover wider vertical
angle range. I have used slanted polarization quads with good results and I am
willing to pay small 3 dB pealty for the better coverage and fewer nulls in the
pattern (in order of 10 - 20 dB). Plays well in the ocean front locations.
After waves go through the ionosphere, who knows what polarization they are.

>People with a deep interest in this topic might benefit from the new

Thanks for the new + one, I have not explored it yet, but looking forward to
use it and play with 2m (hard) models to verify few things, including insulated
wires in the Quad elements.

Hi Gary,
I use my 75 m antenna, which tops out at 70 feet for SWL listening. For 99%
of SWL listeners the limiting things are the poor IF filtering and overload
prone front ends. Also, I dont think you see a noise blanker in a sub $300
radio.

I have had a light duty KLM 7 el 6m beam up for 20 years. During this time
it survived a 96 mph storm that felled trees all around it. Never heard any
vibration from it, but that may be because I braced the boom to the mast
with two 5 foot lengths of 3/8 Al. Had it been copper, and it was still up,
it would look like hell. I don't think hardware store Al would be a problem
on 6m elements. What you don't want to do is to make a big hole in it for
the mounting screw.

I should have stated that more clearly. What I meant was, none of the elements of a yagi are resonant, except perhaps the driven element. My point was that the elements except the driven one(s) must be above or below resonance, or the yagi isn't a yagi.

I have also seen a commercial yagi with the driven element longer than the reflector, so it likely wasn't remotely near resonance. It was also a very poorly performing commercial yagi, but that's a different matter.

If you're talking about "ridge vents" I think they're typically
plastic -- it's cheaper -- but you should be able to figure that out
by looking at them up close. Or check a roofing supplier.

A piece of wire would probably be more predictable and measurable.

Hi OM
Many antenna designs work well.
What they often have in common (besides location) are resonance and matched impedances.
You can make a resonant antenna in many forms. It's impedance will vary but will always be resistive by definition.
Impedance matching transformers work. I like toroids; Low radiation, wide bandwidth.

Reactive components are not necessary and contribute to losses anyway;
I learned that fact the hard way while sorting out the last of the bazookas on this very newsgroup.

Do you have 66 feet? Then a simple dipole is the best choice. If you've only ~50 feet, droop the ends.
Feed it with 50 ohm coax, spin 8-10 turns about your hand and tie it together at the feedpoint.
(Choke balun.)
Be preared to walk back-and-forth as long as it takes to trim the lengths correctly.
Resonance is everything.

Hi Al -

Your antenna is excellent in every way. I have two of them
that I'm thrilled with. And after our local ARES/RACES group
saw mine, they ordered ten more for other members of the group.

I confess to smiling a bit when I found out that my J146/440 at
20 feet is about 6 dB stronger into the local repeater than our
EOC station's Comet "gain" antenna at 50 feet. (Obviously, this
cannot be a direct A/B comparison; but both stations have a clear
shot to the repeater, and they are closer to it than I am.)

Don't let the nattering nabobs of negativism in this NG get you down.
Many of them are so stuck in their ways, I'm surprised they haven't
reprised their stock answer of "use ladder line and a tuner to feed
a 135 foot dipole" as the hot ticket for 146/440 coverage. ;-)

The T2FD (Terminated Tilted Folded Dipole) was developed by the US Navy after carrying out experiments using terminating resistors. Numerous variations have appeared over the years, usually accompanied by warnings that as a transmitting aperiodic multiband antenna, its performance may leave something to be desired. This is because the transmitting power may be wasted in the terminating resistor.

As mentioned previously the antenna developed from US Naval experiments to broaden the bandwidth of a folded dipole to a reasonable degree. The was first described publicly in 1949, after Navy Captain C.L. Countryman tested it for long periods in California during WWII. The T2FD (also known as a tilted, centre fed, terminated, folded dipole) can offer claimed gains of 4-6dB over a dipole, depending on the frequency, although 1-3dB is nearer the mark with some frequencies exhibiting 1dB, as the resistor absorbs the RF power in transmission. The main attraction of the T2FD is not its gain however; it's its broadbandedness. It was, and still is, being publicized in journals as a broadband aerial suitable for use between 3.5 and 28 Mhz. In addition the T2FD has some attractive properties in terms of noise reduction, which some long wires / dipoles and ATU combinations are susceptible too.

In addition the T2FD can be used at higher frequencies than its design frequency. Some sources claim that it can be used over a range of 5 or even 6:1, although my own observations indicate 4:1. None the less a 40-meter version will cover 7Mhz to 25 Mhz, with some useful performance up into the 27 Mhz CB band.

See http://www.gb4iom.co.uk/new_page_4.htm for more information.

I'm working on CW and can copy a little if it is sloowww. Anyway, the band opened up this afternoon, and I made my very first DX contact with a QSO with K7BTZ. He was QRP at 2 watts! I was running in the 50-watt range.

Thanks.

In all but the sandiest soils, it could takes hours and hours of steady rainfall to soak the ground more than a few inches. While good bonding is arguably much more important than chasing a few ohms of earth ground resistance, a dry hole is not much use as a ground point. I chose three of my four (main) station ground points where it is always wet in the thunderstorm season: the electric service ground and a bonding rod near it are next to the HVAC condensate drain. A third one is next to a fish pond in a naturally low and wet area. And the fourth main ground point has to be watered and salted. To our poster in Alaska, I would suggest asking the Electric company how they obtain good grounding in your particular area. And then make sure you bond whatever system you sink in the ground to theirs as well.

Best regards,

Jack Painter

I've never needed an rf ground for a base fed half wave. A decoupling section with radials is an option to reduce feedline radiation..Not required to work though. MK

I live in a suburb. My dipoles and long wires had so much noise that I hardly ever would listen to HF. Once I read about the noise immunity provided by a T2FD antenna, I constructed one to try. It was the best thing I could have done! It made HF livable in my high noise urban environment. I almost don't notice the noise I had before. I am able to pick up signals that my neighbor with a tri-band 3 element yagi is unable to hear due to his noise.

I would recommend this design to anyone combating local QRM.

This is an interesting question, and i'd like to see you folks discuss
this one a bit.

The reason being that regular J-poles (not the super J) are supposed
to be good for urban areas, where there are lot's of buildings in the way
and such. But this implies that J-poles have a lower angle of radiation
than say, a regular dipole.

But then, so do 5/8ths. So i think the question is really:

Which antenna has the lower angle of radiation? OR:

Which antenna has the higher horizontal gain in dB? or the
higher effective radiated power for a given test transmitter?

Slick

4367. Home Brew Resistive Return Loss/Reflection Coeff/SWR Bridge?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-22 11:35:08 UTC
From: Paul VK3DIP <pmcmahon@telstra.com>
Message-ID: <MPUBc.49613$sj4.22869@news-server.bigpond.net.au>
Source record: 93022

Hi,
I have been trying out a couple of home made resistive bridges to measure Return Loss/Reflection Coeff/VSWR and have noted that there seems to be a few basic types and would be interested in collecting a few comments from others who have more experience with them than I. I should mention that I am mainly interested in using these at VHF and up so have tended to discount toroid/current types, and am interested in as wide a usable frequency range as possible so also have not looked a lot at transmission line style directional coupler ones either. If anyone has any comments on those assumptions I would also be interested.

The first and simplest type I have seen in places like the ARRL Antenna Handbook and places on the web like
http://www.g4wif.fsnet.co.uk/q_tech15.htm
and
http://www.pollak.sulinet.hu/electro/hidak/hidak.htm

These are a basic resistive bridge usually all nominal 50 ohm resistors with a built in diode detector. The theory/maths behind these is straight forward and seems pretty obvious by just treating the impedance of the detector as much higher than the 50 ohms of the rest of the system and just ignoring any effects from it.

Then there is a variation, the best example of which I have found seems to be a circuit given be Joe Reisert in his VHF/UHF techniques column in the old Ham Radio Mag (June or July 1996 I believe) which is basically the same as those above but has an additional 50 ohm resistor across the centre of the bridge setting the impedance of the in built diode detector. In the versions I have built (using surface mount components etc.) this does seem to work better, or at least be more well behaved, than the more simple ones, but while I can readily see how this works for detecting balance, the maths for unbalanced (ie non 50 ohm load) cases gets quite a bit more difficult.

The final variation is as found in versions such as that of Jim Ford in September 1997 QST, or as a v/uhf version at
http://www.webx.dk/oz2cpu/radios/swr-bridge.htm
This variation seems to remove the built in diode detector and replace it with a 1:1 balun either of the transformer or choke type and then use a separate external (50 ohm) detector. So mathematically I would think it is equivalent to the Reisert version, but perhaps there is some advantage to the explicit balance of the detector.

Any pointers to a theoretical treatment of these last two types, or other comments would be appreciated.

Sorry for the long post and thanks in advance.

Paul VK3DIP

You lost me Mark. You have a vertical half-wave wire fed at it's base.
You have an unbalanced L/C network which matches the very high
feedpoint impedance to, say, a random length of 50 ohm coax. What do
you do with the coax braid and the ground side of the tuner?

<< >My only problem with J antennas is WHY. I can more easily build a 5/8.

What your really asking is why a half wave vs a 5/8ths?

The best answer I can give is a 5/8ths REQUIRES a groundplane to
work at all correctly and that makes it more metal and complication.
Yes the 5/8ths offers _some_ additional gain but for simplicity the
end fed dipoles (all the J varients) do not require a ground plane and
are more compact in general shape making them a better candiate
for steath or portable ops.

Seriously if I were going for more gain than the OSJ the antenna would
be a 4 bay dipole for the same reasons. Rugged, simple, excellent
gain and good radiation pattern. The 5/8ths does not offer enough
gain increase to make it worth the effort when a 5.6db colinear or 4
bay dipole offers significantly more.

Allison
KB!GMX >>

Wow, Good Answer, I totally agree.

I tested several different 5/8 wave antenna, I even made a
prototype that worked as well or better than any of them, and
looked better. But comparing them to the OSJ it was hard to
tell the difference, maybe a 1/2 "S" Unit in favor of the 5/8 wave.
With the difference in cost to make, (Labor & Material)
it just did not see worth the effort to me.

What I have become stuck on is the claim of constant current along the
length of the antenna - or 80 percent as claimed. How does this work? I
don't profess to know much about these matters, but if the current stays
the same, then the voltage must too?

And i still can't figure out how such an efficient antenna "melts". 8^)

4371. Scanner sensitivity and path loss?

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-22 15:44:16 UTC
From: achilles03@hotmail.com
Message-ID: <fef44ceb.0406220744.5ece04bc@posting.google.com>
Source record: 93026

I was wondering what's an accurate estimate for scanner sensitivity? I've got a Uniden BC180, and the owner's manual doesn't list that information. I was wondering what a good value would be to use in order to do some path loss calculations. I've heard 1.0 uv is a good conservative estimate. Is this too low?

As a second question, what's the approximate margin needed to make out audio? I've heard for data 20dB margin has a link reliability of 99.9%, and 30dB margin yields 99.99%. I imagine to make out audio without too much difficulty, it'd be much less.

Thanks in advance for any insight!
Dave

Looks pretty good. What do you think about using a bigger piece of PVC
and putting the whole choke _around_ the bottom of the ladder line instead
of off to the side (coaxially). Should make it lower profile - all most,
but not quite centered on the SO-239.

Hi Steve,

Thanks for checking it out.

Not sure how the mod you suggest for this will effect the SWR?? There was a slight change noticed just moving the choke to the position it is now. But it's something to think about, and thank you for the idea. Could become a new project too.

I built a j-pole kind-a like this, but was made of 300 ohm TV twin lead ribbon cable. Over 5 years ago now. Everything inside PVC. Choke just below the antenna. Still works great. We use it every day!

That's a VECTOR Network Analyzer, and it's not 2 meter compliant without narrow band up/down converters and accompanying filters.

Anyone can make a "constant current" dipole, just by making it small
enough in relation to the wavelength of the frequency it's to be used for.
Of course, as has been pointed out here many times, feeding such an antenna
would be difficult to impossible, and bandwidth would be small, but you can't
have
everything.
Some theorists in the late 1940's did some work on the fundamental limits of

small antennas. There are one or two papers available on the web if you search

for "small antennas" with google. People who think they can make a small (in
terms of
a wavelength) single radiator antenna, with good efficiency, and a large
bandwidth,
that doesn't have to resort to feedline radiation to achieve its aims,
would do well to read these papers before making themselves look silly by
claiming
the impossible.

Source record: 93032

Sorry Roy but I disagree. Well,... I agree with everything you said
except for the "No" part and the conversion equations. You left out
one part too. The RCP and LCP components of an elliptical wave are
not equal otherwise they would collapse to a purely linear wave.

Here's an example I came up with.
Let E_elliptical = x + 2*j*y (left hand elliptical)
E_elliptical = RCP + LCP
= (a*x - j*a*y) + (b*x + j*b*y) = x + 2*j*y
equating coefficients...
a*x + b*x = x
-j*a*y + j*b*y = 2*j*y ==> -a*(j*y) + b*(j*y) = 2*(j*y)
or
a + b = 1
-a + b = 2
solving for a & b
a = -0.5
b = 1.5
so
RCP = -0.5*x + j*0.5*y
LCP = 1.5*x + j*1.5*y

which clearly isn't
Right Circ E = 0.5 * (Eh - j Ev)
Left Circ E = 0.5 * (Eh + j Ev)

Regards

Dario

I recently installed a RS glass mount antenna on my '96 dodge Intrepid. The area I chose was near the bottom of the rear window.

I get terrible feedback into my car radio. It is either coming in via the speaker or the cars antenna.

Any way to eliminate interference without removing antenna or if I have to remove it will any of the reinstall kits work with the R/S model?

I was looking at the double-sided tape and that seems to me that it might work ok?

If they believe W8JI et al claim that current through the loading coil is constant, then they would claim that they made the current constant. More on the subject check

Absolutely false! I said ***IF*** it's Z0 was 40 ohms, then the results
you gave were predictable. You continue to be ignorant of the implications
of a conditional statement. May I recommend, "Logic, an Introduction", by Ruby.

Here's a refresher: If the 'IF' part of a conditional statement is false,
then the 'THEN' part of that conditional statement is true, by definition.

My statement went something like this: If the Z0 of your transmission line
was 40 ohms, then those results are perfectly predictable.

That is a perfectly *TRUE* statement under any and all conditions.

If you don't understand that fact of logic, please study and learn it and stop
misquoting me. If you do already understand that fact of logic, please stop
lying about what I said. Misquoting and lying are *both* unethical.

The 1 uv is fine for the calculations. You may even be able to go as low as
.5 uv . The lower the number the more sensitive the receiver . Not sure
what you mean about the margin to make out audio. For FM singnals .5 uv
should give you good audio with a trace of noise and at 1 uv it should be
almost full quietning (for FM that is all the hissing noise should dissapear
out of the audio) .

Hello,

I think that I have solution for your question, exactly what you ask, Home brew Resistive Return Loss....SWR Bridge. The article was written by the S53MV in Slevenian and Croatian language, so some translation should be done for you (or you prefer to learn Slavic language HI). The bridge is capable to measure up to 2.5Ghz without any problem, cheap design and awailable material for building, can be done in one afternoon.

Well, I think that just shematic and most important the gama/swr/ar/a table is what you need and the rest you will figure out without any problem.
Ok, I will scan for you just one page and if you are intereste the rest can be done as well.

Meantime, check this page, almost the same design but with SMD components:
http://www.pollak.sulinet.hu/elektro/hidak/bridge/how_to.htm

Tom, I wouldn't be so quick in using the term " impossible" if I were
you until the facts come out. He has already stated that he has a
distributed load antenna which he referres to as a two dimensional
helix, which I see as a meander line on a circuit board. This
ofcourse, provides an antenna of very small size which has some
drawbacks. But the inventor states that the design is a combination of
known ideas which may well be a method of overcomming initial
drawbacks. After all a University have placed themselves behind the
inventor and most of us did not go to University on a platform of
disbelieving our professors . Even if it all turns out to be a
mistaken idea the majority of hams will learn from future interchange
rather than tagging along with those who believe all is already
known.Usually the best inventions are an amaqlgamation of all the good
observations noted in otherwise bad ideas/inventions made by somebody
who looks for every morsel that is new and is
resourceful enough to connect the dots before it becomes obvious to
the followers.It is rare that someting that comes along is totally new
in its entirety.

Ridge vents can be constructed of a variety of materials, including roof shingle material. I use a homebrew attic trap dipole run under my nonmetallic ridge vent. I have a web page about the antenna at:

4387. 40M V Beam question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-23 00:41:12 UTC
From: Bob Wood <bobw@zianet.com>
Message-ID: <10dhlq1m3vs6be7@corp.supernews.com>

V Beam antenna question

I want to put up a 40M V Beam antenna to enhance communication in one direction only. From the limited design information that I have found, I am thinking of 3/4 wavelength on each side with a horizontal separation angle of either 72 degrees or 120 degrees. I have seen both separation angles listed as optimum for maximum gain. I was wondering if anyone knew for sure which angle would produce the best result. Also, and actually most important, I need to have some idea of what the feed point impedance might be. I can feed it with ladder line or good coax and a balun but I am not sure what balun to use or would it be better to use ladder line? I sure would appreciate any guidance on this antenna project.

About what I expected. If someone states something truthfull in this group, no one responds. And it as a group you are all, even Roy, obviously subject to this. No one bothered to even think about what I originally said, or try to see the tongue in cheek.

I guess if you can't argue, it's no fun. I don't blame you all for that, but it is interesting to observe. And sad.

That`s usually right. The reflector is lengthened and directors are shortened to conveniently produce phase relations which determine reinforcement or repression in directions as desired.

However, this is not the only way. Commercial broadcast curtain antenna arrays use parasitic elements which have the same length as the driven elements in some instances. Short-circuit stubs repalace drive lines in the parasitic elements, and these are adjusted for the desired phasing instead of adjusting element lengths.

Best regards, Richard Harrison, KB5WZI

Use a line of any number of 1/2-wavelengths to connect the antenna to a VHF admittance or impedance bridge complete with signal source and bridge detector (VHF receiver). Measure away and record your results.

I agree with most of G4FGQ`s response. You can expect the antenna`s environment to affect its performance and impedance. I suggest the transmission line which is a minimum integral number of 1/2-wavelengths as required to connect your bridge to the antenna as an alternative to Reg`s ladder. A 1/2-wave line repeats the impedance connected to its end.

Best regards, Richard Harrison, KB5WZI

A true V beam is a minimum of one wave per side. And that minimum is not
much of a V beam...I'd have to double check, but with 3/4 wave per leg,
IE: about the same as an extended double zepp, I think you would have
the most gain with it straight like a normal EDZ. appx 5.1 dbi
bidirectional. I bet your gain will drop off if you try to set it up
like a V beam. As far as the feed impedance, it will vary per band. Not
really a major issue. Just treat it like any other balanced antenna fed
with ladder line. If if tunes, fine. If not, you might need to vary tyhe
feedline length a bit. You could feed with coax for a 3/4 wave per leg
antenna, "also 1/4 wave per leg on whatever band.." , but it would be
better to use a ladder line for all band use. MK

Using the usual "gamma loop" feed I generally prefer for those, the coax shield is connected to the "ground" side of the single turn coil. "appx 9-11 inches dia. for a 10m version" I usually make these from 3/8 tubing... That point is at ground potential as far as the mast, base support, etc..The other side of that coil is connected to the base of the radiator. The center conductor taps the single turn coil at the point for best match. A capacitor from ground to coil "hot" side is optional. In general you use about 50 pf for a 10m version. Double for 20m, double again for 40m, etc... I use a piece of coax for those. "open end, don't short" For 10m, it's only about a foot or so long...Look at a cushcraft 10m ringo. "model AR-10". They have PDF manuals on the web with pix..That is the same basic design I use. They also make 2m versions...BTW, I make these from tubing, and are self supporting. Rarely use wire...These antennas work quite well. Good 10m antenna...The higher, the better..Add decoupling, even better, but not required to work..MK

My roof vents are metal. But there are so many other things like electrical wiring, metal air ducts, cable TV lines, ect in the attic that wire vents are just one more thing in the hidden antenna pattern (what pattern)... ;)

>An outside antenna seems unlikely as it is a newer subdivision

Depends. Lots of ways to hide em. My roof peaks at about 30'. One of my antennas is made of enamel coated magnet wire that is virtually invisible when laying on top of my red tile roof.

>or a peak of the roof, indoor dipole.

They work too. I also use Hamstick dipoles in my garage attic. There is no reason why you shouldn't enjoy your hobby even in a HOA restricted area. I do. In fact my neighbors have yet to figure out I am a ham, which makes it nicer than my old place where I got blamed for everything...

First of all, thanks for the info!

What I mean by margin is:

Transmit strength (dB) + Receiver sensitivity (dB) - path loss (dB) =
margin (dB)

If I understand what you're saying correctly, with a margin of 0 you
can still make out decent audio? I thought there'd still be too much
S/N ratio or not enough "signal" for the amp to work with in order to
get "hearable" audio at 0 margin?

Thanks again!
Dave

<< I recently installed a RS glass mount antenna on my '96 dodge
Intrepid. The area I chose was near the bottom of the rear window. >>

First problem. Higher, higher, higher! I have one for APRS, it is installed as high as it can go on the side glass of the vehicle. It is also as far away from the car radio antenna as is possible. Antenna is thus in the clear to minimise interference.

The ONLY reason I used it is due to the dualband VHF/UHF on one side of the rear hatch, and the screwdriver on the other side (ran out of mount space!). The glass mount is a compromise antenna with lower efficiencies than a standard 1/4 or 5/8 wave deck mount.

That said, get a reinstall kit and mount it up as high as you can on the glass. It WILL work, just not that great.

That's a nice trick. Of course that still means they aren't resonant since you just displaced the "center" of the element. Seems a good way for a broadcaster to be able to adjust the pattern if needed after construction.

I seem to remember an HF wire antenna project that used that method to go from driven plus reflector to driven plus director to get a reversible beam. I also remember a set of 5 slopers that were in the ARRL antenna book or handbook that could be steered.

Oh well, way off topic here now. cul

Your concerns, no. The birds, yes.

I push 1kw out of a 1/2 wave horizontal dipole and the birds never choose it as a resting place. Down near the ground, it hasn't impeded the population of several Finch, Cardinal, Northern Thrush and Robin families.

I just did some reading based on what you said. The sensitivity is
actually based on a minimum S/N ratio... and if I understand
correctly: if an audio signal comes in with a strength of 1.0uV and
the receiver sensitivity is 1.0uV, it will be understandable?

Thanks again!
Dave

I've been out of town and not following this thread. Here's what I do
for HF - knowing the length, VF, and attenuation factor of ladder-line.
Trim the laddder-line until the impedance looking into the ladder-line
is purely resistive. Draw the corresponding SWR circle on a Smith Chart.
Using the line-attenuation factor, draw an SWR circle outside of that
one. The antenna feedpoint impedance lies on that outside SWR circle.
Calculate the exact electrical length of the length of ladder-line
being used and use the Smith Chart to track from the purely resistive
feedpoint impedance back to the antenna feedpoint impedance on the
largest SWR circle.

Of course, the accuracy of the final indirect measurement depends upon
the accuracy of all the parameters used in the calculation. My accuracy
has always been good enough for what I needed.

I've never done it with coax but I assume the same principles apply.

I've tried to chase Starlings away by applying 100W to my 20m rotatable
dipole. Some fly away. Some just sit there and tingle, jumping around
and ruffling their feathers. On my antenna, the only place guaranteed to
chase away a bird is the feedpoint with one foot on each side.

Kraus describes adjustment of the phase between driven and parasitic elements on page 320 of his 1950 edition of "Antennas":

"The parasitic element may have a fixed length of 1/2 wavelength, the tuning being accomplished by inserting a lumped reactance in series with the antenna at its center point."

In my case, the "lumped reactance" was a tuned stub adjusted to the desired phase difference between parasitic and driven elements as indicated by an RCA WM-30A phase monitor.

Maybe get a rent a hawk or the duty owl.

Seriously -- the Ham stores sell a good looking owl to put on towers --
don't if they scare away the other boids -- but they look good (;-)

Woudn't the bird consitute but a tiny capacitance to ground and thus not experience an RF burn of consequence?

4410. FM Antennas

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-23 15:48:19 UTC
From: StrikitRich <strikitrich@nospam.net>
Message-ID: <strikitrich-3A08E7.11481923062004@comcast.dca.giganews.com>
Source record: 93065

Pardon me if this is the wrong place to ask this question, but hopefully I can get an answer here.

What would be the best type of antenna for receiving FM radio stations up 80 miles away(Tampa to the north, Fort Myers to the south)? The antenna would be mounted outside, up to 30' high. Would an omni-directional antenna work, or should I stick with a directional?

My TV antenna is up about 55', but the amplifier has the trap on and I can only get the strongest of the signals.

Thanks in advance, SR1

Cecil, W5DXP wrote:
"Trim the ladder-line until the impedance looking into the ladder-line is purely resistive."

Sure. The line is purely resistive at resonant lengths where the power factor is one. No reactance. A 1/2-wave is a resonant length.

Charlie Wright, an A.D. Ring and Accociates engineer used to drive our German engineers crazy, telling them that slopes on the autobahn used coble stones because they didn`t know how to pour concrete on an incline.

Charlie also got to a group using an RCA WM-30A phase monitor to tune parasiitic elements in a curtain array. Most medium-wave directional stations at the time used a WM-30A as a phase monitor, just as shortwave stations used them for tune-up.

Charlie had used the monitor for years and knew it had an underated resistor which sometimes failed. The group had upended the chassis and Charlie offered to help troubleshoot. The Germans acquiesced.

Charlie asked for voltage measurements from unrelated parts of the circuit, took out his slide rule and feigned a few calculations. Then, Charlie pointed to the defective resistor and said: "Change that one."

The crowd shook its collective heads but complied. The monitor miraculously sprang to life again. Charlie chuckled to himself as he left the incredulous crowd.

Best regards, Richard Harrison, KB5WZI

At 207" in boom length, it may be a bit of overkill for my needs. The
antenna will be fixed, which is why I was wondering about
omni-directional ones.

Dear Bob Wood W5QCP:
Nice to see a name and call on a question.
Might you be asking about legs of 3 to 4 wavelengths on 40 meters?
Assuming that is the case, what is optimum depends on height and desired
take off angle (TOA) of the max. radiation.
Most often, three masts of a certain height are available and one
needs to deal with the limitations that result.
What are the expected heights of the masts? 73 Mac N8TT

Note that with one more mast, you will have a rhombic antenna, which is
a little better behaved and much more easy to terminate.

They can be wonderful engineers, however.....
My 999 story: A major automobile manufacturer tasked their German branch to design a new transmission for a "sporty" car. Prototype arrived at the proving grounds and looked anemic. Transmission was placed into prototype car. Everyone went to see the first use. Driver wound up the engine to red line, and loud 9 9 9 was heard as clutch was engaged and shrapnel was produced. US engineers turned to German engineers and said: "We told you how it would be used - now believe us."
An antenna system was used to send data back for analysis. 73 Mac N8TT

Thanks for the comments Mark. I do appreciate your taking time to give me some advice. I only have a limited space around my home so can't put up a one wave per side. I am currently using a sloping dipole and doing fairly well but need to improve the reception to cover Texas, Arkansas, Oklahoma and Louisiana for Navy MARS region nets. I saw an article somewhere that indicated a V Beam 3/4 wave on a side would provide 3 dB gain over a dipole in one direction. I will have to research it some more but it is really difficult to find information on V Beams on the net. If you do discover any more info I sure would appreciate you sharing it with me. Thanks again,
73, Bob

Hi Art,
he may very well have produced an antenna that works as
advertised. Time will tell. However, in evaluating the claims of anyone
who invents something new it is always advisable to compare those claims with
current theory before accepting them wholeheartedly. It isn't impossible to
make a small, useful, antenna - the small-in-terms-of-wavelength loop
is a case in point - but to make a small antenna with all the characteristics
of a large antenna strains the credibility. It sounds as if this gentleman
is trying to take advantage of the properties of the double-tuned circuit in
order to achieve a larger bandwidth while maintaining good efficiency.
If so, it's an interesting idea and I hope it works, but I'm not going to
get excited about it until I know more, such as, what happens to
the radiation pattern when the current in the top part of the
antenna is out of phase with the current in the bottom
part? Does it then radiate straight up, or does he have some
method of controlling the phase so it doesn't do this?
73,
Tom Donaly, KA6RUH

Ten Tec sells a v-beam antenna. You can download the manual at
http://www.tentec.com/3402.PDF

It might be helpful as far as setup info goes.

Stick with a directional. You'll probably need a log-periodic to
handle the full width of the FM band - a Yagi/Uda would be great for a
single frequency but probably would not have the bandwidth necessary
to do a decent job across the whole band.

My TV/FM log-periodic at about 35' does a decent job of bringing in
stations from San Francisco (about 40 miles away). 80 miles may be
pushing it.

>My TV antenna is up about 55', but the amplifier has the trap on and I
>can only get the strongest of the signals.

You might want to consider changing over to an amplifier which doesn't
have a trap, or whose trap can be switched on and off, and just use
your existing antenna.

Source record: 92980

Gain loosely refers to 'better than' .
If you have an antenna with 2.5 dbd gain then it has 2.5 db gain of a
'dipole' (the last 'd' in dbd). (good).
"Unity" is another way of saying 'one'.
"Unity gain" means its no better than whatever you're comparing it to - and
no worse.
Unity gain is good if the antenna has other redeeming attributes (like
being smaller or less noticeable).
Unity gain is not good if you're expecting it to outperform the antenna
you're comparing it to.

The term 'Unity Gain' is not 'reserved' for any particular type of antenna.

>>bandwidth, that doesn't have to resort to feedline radiation to achieve its aims,
>>would do well to read these papers before making themselves look silly by
>>claiming the impossible.

It would seem that way to me.

From the description, I got the visualization of a hollow tube, with
perhaps three main parts. A center conductor, which would be the helix.
outside of this would be a vertical wire running from top to bottom. I
would assume these to be ground wire, and serve as half of the capacitor
function. There might be some version of little hats attached to the
helix from top to bottom as the other part of the capacitor(s).

Will it work? "work" is so subjective.....

After all, birds sit on high voltage distribution lines with no ill effects.
At some point, I guess, corona leakage becomes a factor. You don't see them
sitting on the 100kv+ stuff.

What do you have now? A directional antenna will not work N and S unless you rotate it. Off the back it will be worse than a dipole. If the TV antenna is on a rotator, it sure would be nice to get rid of the trap, unless there is some station very close to you. Before you spend a lot of money, try a dipole running East and West. 80 miles is beyond normal range, and probably nothing will give you a good signal all the time.

I have to use the trap, or I lose a couple of stations. The amplifier is 50'+ high, and scurrying up and down the tower isn't feasible. Range is actually 60 miles north and 40 south.

At this point, I'm thinking of strapping a log-periodic onto the side of my TV tower. If I mounted it to the same mast as the TV antenna I can use the rotor, but this will block my access to the TV antenna.

I installed a glass mount for day to day since the terrain is flat and repeater coverage drops off so efficiency is not an issue. I also wanted to get the car in a nd out of the garage and the antenna is a dual band antenna.

For better performance, I used a half wave.

Still getting the thing off of the glass and moving it is the current concern.

Keith

removing a glass mount antenna is easy
razor blade
it's drilling a hole in the roof of your car that's hard

I did it, and I'm proud to admit it
think of it as marrying the vehicle, unless you sell it to another ham
at 90,000 miles my Durango sports a 200 watt Kenwood (NO TUNER!!)
and still has the original brakes (I don't stop much)

plus a Kenwood 742 on 144, 222 and 440
with a Comet tri-bander amid the roof, a Tarheel and 103" whip on the right
hip for low HF
(with a toroidal transformer that gives 50 ohms resistive on 20, baby)
and a Hi-Q that tops at 6 meters on the left hip
I also have a humongous Hi-Q for 160-80 when needed
what fun
73
H.
NQ5H

At that range you will probably need *both* more altitude and a
high gain directional antenna to get full limiting on FM. If you want
both directions for both Tampa and Fort Meyers you will need either a
rotator or (maybe cheaper) two separate yagi's.
If you are very close to the geodesic connecting Tampa and Fort
Meyers an elegant solution would be to homebrew a sharp bidirectional
coalinear array.

> in one direction.

While, classically, V beams have longer sides, I do know that a 3/4
vertical W/ground plane has a major lobe about 50 degrees above the horizon.
There was an antenna described by Inagaki (sp) some years back using this
characteristic to advantage with a corner reflector to obtain something like
18 dB gain and a nice 50 ohm Z. It also had a considerable minor lobe at
the horizon - obviously the main lobe remnant from "when it was a 1/4 wave",
so to speak.

If this can be generalized to a configuration where the "ground plane half"
of the antenna is supplied by another 3/4 wave element, then the V angle
would be about 100 degrees to get the two lobes to coincide. Modeling with
EZNEC should be easy...then there's the "how high is it" issue.

> > Woudn't the bird consitute but a tiny capacitance to ground and thus not
> > experience an RF burn of consequence?

Let's see here...
First, The bird must have some fundamental capacitance to the rest of the known universe. lets take a stab and say it is 10pf since he is pretty far away from almost everything. I'm sure there is a formula for the capacitance of a 4 inch diameter sphere somewhere...
Second, Lets model this as 10pf to ground.
Now, what's the current through this 10pf at the tip of the antenna (assuming his foot-element contact resistance is well below the Xc)...We're at 20M, 15M or 10M, so, without resorting to math, Xc is pretty low, in general terms. Hmmm could be substantial even at 100W, no?
Sounds like his poor feet could indeed get enough to make life difficult.

> After all, birds sit on high voltage distribution lines with no ill
effects.
> At some point, I guess, corona leakage becomes a factor. You don't see
them
> sitting on the 100kv+ stuff.

Completely different situation due to the 60 HZ. The 10pf would lead to negligible current... "Just don't get one foot on each wire, Son. Your Unkle Tweety did that and there was a loud pop and he was gone in a bright flash. Some feathers and a bad smell was all that remained."

"On the other hand, son, getting to the top of one of those really high man made trees with wires and your feathers'll all stand on end! Its really cool! Just don't let your mother catch you doing that."

> the receiver sensitivity is 1.0uV, it will be understandable?

If you are using FM then you will see a specification of say .5uv sinad or .7 uv for 20 db quieting. Usually that is about the same real world sensitivity unless I have it backwards for sinad and quieting. This level is for understandable audio. FM has a threshold level in that you get a bunch of noise with the audio comming out of the receiver tuil you hit the threshold point and then just a small aditional ammount of signal will clear up the audio. Any more signal will sound the same. You should hear the audio just fine at the above levels.

As far as the fade margin goes, the 0 level is what you get for the above sensitivity. YOu will need some ammount above this level to get a good signal all the time. At vhf and above for a distance of say 30 miles you will have a signal of so much for maybe 70 % of the time. To get to the 99 % or more you may need 20 or 30 db of fade margin. Maybe 2 % of the time you will have a stronger signal . All this is due to the way the atmosphere bends the signals.

Some use the NMO mount through a drilled hole.

This allows an easy switch to a cell antenna, and you turn a negative
(ham antenna installed through a hole) into a positive (cell phone
ready).

Birds also sit on high-tension lines carrying many amps at thousands of
volts.
Makes you wonder if it interferes with their built-in compass.

Bob,

Unless the antenna is up in the clear, the full gain, F/B, and F/S will not be realized. You might be better off using 1/4 wavelength per side, rather than 3/4, and get the extra height instead. As to feeding it, open wire line will work quite well, over a broad frequency range, and be virtually lossless at even high SWRs negating the need for a balun and the associated problems. Just one ham's opinion.

73s,

Evan

Hi Dale.

I've also seen the term mis-used by manufacturers when they mean omnidirectional. The antenna may have performance 20 dB down from isotropic, but they'll call it unity gain when it just has the same "gain" in all directions.

A more valid comparision is how much of a wavelength does the bird's two
feet shunt on the antenna wire? I'd suspect the problem would increase with
frequency; becoming very painful in the VHF regions.

i have found mounting these antennas vertically makes them longer lasting...
because birds land on them and bend the elements down when mounted
horizontally.

My situation somewhat similar,watch TV stations 80 to 100+ miles
away, having a FM station 6 miles away and still wanting to listen
to FM stations 50 to 80miles away. I disabled the FM trap on the
mast mounted amp,split the sig in the house,than notched(trap) FM
from the line to the TV. DX tropo last year TV 800miles and FM about 400 miles.

i havent noticed a problem with injured birds on the broadcast towers. FMs up to 100,000 W ERP. (about 14,000 W per bay in my case).
5,000 W AM towers both non and directional including top loaded arrays. not a problem either (in fact i have had birds nest in them)

I have one site that uses open wire transmission lines to feed a 5 tower array... 10.4 amps of RF at the common point. up to 10 amps of base current. located in a wildlife refuge. still no birds frying themselves.

now i have been burnt a few times working on this thing... maybe it goes to show that birds ARE smarter then radio engineers.

Where are you now? Are they all in the same direction?

I saw an article somewhere that
> indicated a V Beam 3/4 wave on a side would provide 3 dB gain over a dipole
> in one direction.

Dunno about that. Sounds a bit fishy to me, but I'm not saying it's
impossible. But consider this...
An extended double zepp, which is .64 wave per side, has almost that
exact gain over a dipole in TWO directions. If you only need 3 db, that
would work, if f/b ratio is not a problem. If you need some f/b and
gain, I would use an array of two dipoles parallel.

I will have to research it some more but it is really
> difficult to find information on V Beams on the net. If you do discover any
> more info I sure would appreciate you sharing it with me. Thanks again,
> 73, Bob

I have some in books, but I don't know what you want to know
specifically..But I don't consider a 3/4 wave per leg antenna a V beam.
It has none of the properties of a true V beam, which is a form of
traveling wave antenna. To really act as a V beam, and have decent gain,
it must be a few waves long on each side.
A single long wire is the simpliest form of traveling wave antenna. It
must be at least one wave, and should be several. A V beam is two long
wires connected at one end. A rhombic is two V beams back to back. They
are all closely related. The longer the V beam or rhombic in WL, the
narrower the angle between the wires should be.
A 3/4 wave per leg antenna folded into a V, is just a 3/4 wave per leg
dipole in a horizontal V config...Having straight like a true EDZ, and
using only .64 wave per leg, instead of .75, should actually give you
the most gain you can get with that antenna size. Thats the way I see it
anyway...I'd forget about V beams. You probably don't have the room for
a real one. There are better options like the phased dipole array, or
the simple EDZ itself if f/b is not an issue.. I've run the phased
dipoles on 40m. It's almost like having a 2 el beam that can point in
two directions. More than that if you play with the different phase
options. That would give you your wanted gain easy, and about a 15-20 db

f/b ratio to boot.

Bill,

The claims you make about this wire don't sound right.

Stranded wire does emulate a conductor with the same, or slightly larger, diameter. However, the increased, self-shielding surface area is very prone to oxidation via mositure. Ergo the conductivity decreases somewhat over time. You compare to #14 wire, which is fairly thin in this application. Perhaps you should compare to a solid conductor of the same diameter, such as #10?

Stranded wire is used on LF and VLF transmitters because it is economically impractical to make wire with very wide diameters. However, it is not the STRANDING of the wire that's important, per se, but the overall diameter.

It's a good product, but the reasons you state for buying it don't make sense to me. Perhaps you have some data that shows superior gain and bandwidth of stranded copper compared to regular copper of the same diameter? I am not familiar with any measurable differences in the apps you target. Kindly fill us in if I am wrong.

I fear your potential buyers might assume substantial increases in gain and bandwidth from your comments on the description, when, in fact, little benefit , if any, is attained.

73,
Chip N1IR

Thanks again Mark,

I am currently located in South Central New Mexico and all of the stations on the net are East and North East of my location. Since FB ratio is not a concern for me I think your suggestion of an Extended Double Zepp (EDZ) would work just fine. 0.64 wave on a side would work perfectly since the 0.75 wave per side that I had been considering was really pushing the size of my back yard. I will have to look into the EDZ but am assuming that the max radiation pattern would be broadside to the wire which would work perfectly for me. I have enough room on the property to run an EDZ North-South which would provide the East-West broadside radiation and if it has any gain over a dipole, I will be ahead for sure. I know that I do not have enough room on the property to install two elements so I think we will now shoot for the EDZ and see how it works. Thanks so much for the ideas as they have been enlightening.

==========

Sranded wire is also used because it is flexible and easier to erect.

But stranded wire of the same diameter has a somewhat higher HF resistance.
As usual it is skin effect.

Current tends to flow only on the extreme outermost surfaces of the strands.
So the surface area is less than the surface area of a solid wire of the
same overall diameter. The fewer the number of strands the greater the
effect. Imagine where the current flows with only two strands. There is
also the very minor effect of spiralling.

But continue to use stranded wire for its undoubted superior mechanical
properties. If its HF resistance is too high then increase its diameter -
just as is done with the solid stuff. The loss or gain in S-units per lb
weight per mile is not worth the bother of consideration.

Back in the '60's, at Naval Radio Station CKN, we had a number, perhaps ten or fifteen, of multikilowatt transmitters all feeding the antennas through open wire line. The transmitter building was like a huge barn with all the wires running from the transmitters to the antennas. An occasional bird would fly in, and we would chase them out with a broom! We never lost a bird, but the junior hand on the watch would have to sweep out, and in an evening we could count on half a trash-can full of dead flies! The building was in the middle of a swamp area and full of assorted flying insects. Those same flies were responsible for occasional trip-off's of the transmitters, and you could hear frequent snaps if and when they happened into a critical area, for example between capacitor plates, and drew an arc. If you picked up a fluorescent tube, it would light up from all the RF floating around. I've often wondered about how much effect the RF had on me -- although my Ex would tell you I am stark raving mad! :-0

The antenna fields should have been filled with dead birds if the feeders or the antennas themselves were a hazard, but apparently not.

Ah, the memories! Great!

What kind of FM trap are you using? My previous amplifier had a weak
trap, so I used an inline trap with a similar setup to yours. When I
had the amp replaced, woodpeckers wrecked the case, I was told that this
would no longer work, the inline trap didn't seem to work, either. I
was told that the trap needed to be close to the antenna, and inline
before the power source.

What guage is the stuff? All you say is it's 1/8-inch thick. I normally don't buy wire by thickness, but by guage.

Also, is it 100% copper? Or some combination of copper and steel?

thanks,

actually in this case grounded or ungrounded makes no difference. the RF
just burns a very painful hole in what ever part of your skin you carelessly
brush against the hot wires. some of the vacuum variable caps have
adjustment knobs with metal set screws... ouch try to remember to only
adjust with your fingertips touching the bakelite. this is a very old array
built in 1949.

Danny, K6MHE wrote:
"I hot jumped the tower several times."

I`ve done the same in a 5 KW medium wave broadcast station to avoid a burn during transfer, climbing the hot tower with no ill effects.

I`ve also accidentally contacted a 50 KW signal on a 600-ohm line while standing on the roof of a shortwave broadcast plant. That wire really burnt my ear. Glad I wasn`t a bird!

Our shortwave transmission lines carried mostly 50 KW and 100 KW signals, usually at near 100% modulation of the amplitude variety. Our carriers were between 6 MHz and 16 MHz, sometimes higher or lower, depending on target, time of day, or season.

When a bird landed on a transmission line wire he mostly evaporated without a trace except for his claws gripping the wire. There was a puff of smoke and steam during the instantaneous event. The transmitter usually had no visible response. It kept right on pumping out the megacycles. Our transmission lines were coated with bird claws.

Best regards, Richard Harrison, KB5WZI

"---this is a very old array built in 1949."

In 1949 I worked at the KPRC (950 KHz) / KXYZ (1320 KHz) plant at Deep Water, TX.
They shared a main tower which was built for KTRH (740 KHz), which had moved to Cedar Bayou. The tower was near 1/2-wavelength at 1320 KHz and a high impedance for both stations.

One operator responsibility was periodic logging of tower currents. For lightning protection, the RF ammeters were shunted with knife switches which must be open during reading. Since the main tower was so hot at its feedpoint, we had a wooden stick with a bent nail in one end to operate the knife switches. RF burns are unpleasant. This stick would burn a carbon trail to your hand in a couple of weeks and be replaced. The sparks along the carbon trail were spectacular but benign if the stick was replaced soon enough.

Best regards, Richard Harrison, KB5WZI

Hello,

Gain figures are often false and misleading - in the UK if you had told CBers a certain aerial had 10dB gain - they would all buy one. It's just a number plucked from the air in most cases.

The only time I've heard of birds coming out on the short end of the deal was at a VOA transmitter site in Ohio running megawatts of power along open feed lines. I'm sure your maximum forward power wouldn't even approach their reflected power (grin).

Thanks to all; these are nice stories when they show up. Almost a
thread of it's own, hint hint.

Too bad a lot of the current generation just coming online to do rf
systems engineering won't have such good ones to pass on - "Well we
fired up the 1W 5600Mhz biaamp and the female inverse TNC connector on
the antenna side was shorted! The amp got warm to the touch after 15
minutes! It was a close thing. Funny though, the users within 300m
could still get decent throughput."

I worked at KWLO in Waterloo, IA back in the late 70's. It was only a 5Kw station with a five element directional array. During the day only two of the towers were fed and the night time pattern used all five.

During my initial instruction on how to read the current meters at the tower bases, the chief engineer was showing me how to put the meter in the clips and then rock the shorting bar out of the parallel clips that were in the circuit. One side of the shorting bar was always in a clip. then you would read the meter and put the shorting bar back into the clips. After that you could remove the meter.

Well, he was behind the transmitters and the phasing cabinet in a fairly confined space showing me how to do the task. Set the meter in place, rock the shunt out of one clip, take the measurement, rock the meter out of the clips.

How many of you caught the problem in that sequence?

Yup, that is the way he did it. The arc from the clip to the current meter made the prettiest ohm sign I have ever seen. I saw the engineer starting to rock the meter and was already moving away when he broke the connection. The relexes of youth are a wonderful thing.

The only thing that happened to him was that he banged the back of his hand on the inside of the cabinet as he got it out of the way of the arc.

The transmitter didn't even miss a beat on that little shenannigan. It may have shown an overload on some of the warning lights but I can't recall right now.

Yes. Appx 5.1 dbi in two directions broadside to the wires. Or almost
exactly 3 db over the 1/2 wave dipole.

> North-South which would provide the East-West broadside radiation and if it
> has any gain over a dipole, I will be ahead for sure. I know that I do not
> have enough room on the property to install two elements so I think we will
> now shoot for the EDZ and see how it works.

Should do pretty well. Will be appx 84 ft a side. Get it as high as you
can, and preferably set up as a flat top. It will work as as inv vee,
but the gain may drop off a bit. I ran one on 20m one time, and it did
well. One thing about the 40m EDZ.. If you feed with ladder line and a
tuner, it can be used on other bands also. Even 80m should work ok,
being it's longer than a 80m 1/2 dipole. Always use the minimum
inductance needed to get a usable match when tuning the tuner. MK

If you are still uncertain about what angle to use for a V with 1/4 waves per side, you might get alot of insite from how good LPV antennas are designed. The basic idea used for the LPV depends on the pattern from each side of the V to combine to provide good directivity at that frequency where the elements are 3/4 wave long.

I believe the UPLC disrespects amateurs primarily due to our use of
armchairs. And I'm as guilty as any; for years, I've been sitting on my ass
in an armchair!

Well, what kind of logic could you expect from a CEO named Moron(ey)?

From the article"

"UPLC reminded the Commission that BPL is not just another broadband
access platform, but one that enables applications in ways that other
technologies do not by providing enhanced utility applications, home
networking, symmetric speeds, and low latency for a variety of
services. Unique applications will improve the efficiency and
reliability of electric service to utility customers as well as
promote broadband competition for consumers, carriers and ISPs -
saving lives, reducing electric generation costs, remedying the
digital divide and conquering the DSL- cable duopoly."

Wow! This stuff can do anything except restore virginity. And
I'm sure they're working on that little problem.

4486. Help newbie with Channel Master 9512 Rotor - homebrew controller ?

Newsgroup: rec.radio.amateur.antenna

I'm fixing up an older Channel Master light-duty rotor to turn a small 2m wooden quad I've built for my attic, but one of the plastic gears in the control unit disintegrated in my hand during the rennovation. The rest of the control unit is in rough shape too.

I'm thinking of building my own power supply/control unit for this rotor, but I'm not clear on just how these 3-wire units actually control the rotor. Any ideas? I can perhaps make my own simple PS, and figure out the direction-setting power scheme, but getting feedback on the antenna position to prevent over-turn cound be tricky.

Thanks to all who reply...

They certainly will need to find a way of doing that, in view of what
they are doing to (potential) customers, to existing licensed users of
the RF spectrum, and probably to their investors as well.

"The United Power Line Council (UPLC) forcefully replied to concerns ..."

Forcefully -- not truthfully or accurately but -- FORCEFULLY!

"... as well as promote broadband competition for consumers, carriers and
ISPs - saving lives, "

BPL saves lives! What could be more important than that?

"... ignore "armchair amateurs that still use vacuum tube transmitters" "

Ignore the power companies that still burn coal to make steam!

""BPL is an exciting technology with a promising future, but it's dependent
on the FCC to develop rules that will encourage companies to deploy
systems.."

No new rules are needed, because:

"...the risk of interference from BPL is extraordinarily low, ..."

Sounds like the Cranky Old Hams have struck a nerve!!

Frank Dresser

Kevin:

Those 3 wire controllers depend on running a motor in the indicator at the same speed as the rotator, so indicator accuracy is sometimes less than perfect (snicker). Most light duty RatShack rotators use that approach. The rotator itself is typically a split phase AC motor, a common and one phase fed directly, the other through a phase shifting capacitor in the controller. Swap the two phase leads for reverse direction. You may want to consider buying or fabricating a replacement gear to get direction readout. Or adding a separate direction indicating mechanism. Good luck!

Source record: 92946

Bob Wood wrote:
"I want to put up a 40M V Beam antenna to enhance communication in one direction only.---I am thinking of 3/4 wavelength on a side with a horizontal separation angle of either 72 degrees or 120 fegrees."

Arnold B. Bailey catalogs a bidirectional horizontal unterminated Vee in "TV and Other Receiving Antennas" Ends of the Vee must be terminated in their surge impedance for unidirectional response. Bailey gives 800 ohms as surge impedance of the wires in the Vee.

All antennas in Bailey`s catalog are "optimized" for a frequency of 200 MHz (1.5 meters).

The horizontal Vee is center-fed at its apex. So, it opens / closes toward its best directions, since It is unterminated. It is bidirectional.

Bailey`s Vee is several wavelengths per side. Its drivepoint resistance is 160 ohms. Gain is 10 dB. 3-dB bandwidth is 3%. It still behaves as a standing wave antenna without termination.

The Vee is made from two horizontal 35-foot #10 wires for 200 MHz, forming an included angle of 35-degrees (21-feet between outer ends).

At 40m, the wavelength is about 27 times that at 1.5m. So, that`s the scale factor. The wires become about 933 feet long.

The same wire formed into a rhombic is unidirectional if terminated. It only takes one termination resistor, and the rhombic gives 3 or 4 more dB gain than the same wires in a Vee. The rhombic is a little shorter overall than the Vee, too. At 40 meters the rhombic requires about 567 feet overall length and is about half as wide as it is long.

If you can accept a total gain of about only 4 dB, you can have an antenna with much less wire and space. Two parallel center-fed wires, each about 1/2-wavelength, and 1/4-wave apart, elevated at about 1/2-wavelength, and connected together with parallel open-wire line in the plane of the wires will give a drivepoint resistance of near 50 ohms across either antenna.

Which direction is favored depends on which dipole is fed directly and which acts as the directly connected reflector. 3 dB bandwidth is 60%, which is much better than the 3% of the unterminated Vee.

Arnold B. Bailey gives data on page 521 of "TV and Other Receiving Antennas" for the "Half-Wave Antenna and Connected Reflector". He credits P.S. Carter, Proc. I.R.E.,vol. 20, p1032, June 1932.

Best regards, Richard Harrison, KB5WZI

Yes, that is an advantage. Everytime someone asks a question about a receive only antenna on this newsgroup, there are always many responses saying to just put up a piece of wire and run it strait to your radio. That will work, assuming that you live out in the middle of nowhere, have no neighbors and have no electrical appliances. For the rest of us, noise is a consideration and more thought needs to be put into an antenna system.

During my working days in a shortwave relay station, we used to go out to the field to clear off the hanging charred claws on the feeder lines. The birds standing on the feeder line did not know when we will switch on the 250kw transmitters and burnt to death instantly, leaving behind the claws hanging on the line.

Are you sure about that? The Alliance and CDE rotators had an interrupter switch in the remote unit that caused a solenoid in the control unit to advance the indicator pointer. This pulsing took place every 10 or 15 degrees of antenna rotation. The pointer turned in whatever direction the control knob had been turned.

Source record: 92954

Thanks for the heads up. I just sent my "reply" to them as follows--others may like to do so as well:

In response to the Press Release re: BPL
I commented to the FCC that I was opposed to BPL in its current state because it has always, to the best of my research, generated some level of interference in the high frequency (HF) spectrum in the numerous actual deployment tests. Any interference to HF reception has always been unacceptable.

I have heard the interference from some actual BPL deployments, and the interference would make most of the communications in the HF spectrum difficult, especially to the SW Broadcast industry.

The "press release" statement that "UPLC also commented on amateur radio opposition to the technology, urging the Commission to ignore "armchair amateurs that still use vacuum tube transmitters" and listen to the reputable companies and entrepreneurs who are the real experts on BPL" is simply not true, is insulting, and misses the whole point.

Whether tubes, transistors, ICs, or the new computer-driven radios are used, the interference from BPL still makes HF use impractical for most current HF users and listeners. This is unacceptable.

To have the FCC redefine the "no interference" standard to a "fixed limit of level of interference" is also unacceptable.

With satellite, dial-up modem, cable modem, and DSL all providing adequate connectivity today, there is no legitimate need justifying BPL with its interference to legitimate HF broadcaster, military, and amateur communications.

Sincerely,

Gregory J. Knapp, J.D.

Some where around here I have several photos of Cormorants (I think
that's how it's spelled) sitting on the beams. Those are *big* birds
and it shows in the droop of the booms and elements. They didn't seem
to be concerned about 1500 watts.

I couldn't get rid of the darn things. They had decided that was
where they were staying for the night. When I'd chase them off they'd
just come back. Worse than a load of ice. They are bigger than ducks
and there were 8 or 10 of them up there.

Being a non-US amateur this really doesn't concern me, but after reading the media release I couldn't resist having may say on her comments about amateurs! My reply to her is copied below.

Cheers

Martin, VK2UMJ

Dear Ms Patterson

Whilst I am not a US citizen and so the current issue of BPL in the USA does not concern me, I am what you incorrectly referred to in your media release as a"armchair amateurs that still use vacuum tube transmitters" and as such, I feel an apology from you to all amateurs, worldwide, is warranted.

Firstly, it is obvious that you are merely an "armchair media officer" that has absolutely no idea or concept of what amateur radio is, what equipment we use, and what knowledge we have. Your comments are defamatory to the entire hobby, worldwide, and are proof that the UPLC hav absolutely no interests other than their own profit margin. It seems that 'truth' is a concept that is lost on people such as yourself.

The level of your own technical inadequacy is further proven by your comment in the release: "Moreover, these systems will incorporate adaptive interference mitigation capabilities that will effectively remedy any

interference that might result to fixed and mobile operations in the High Frequency (HF) band (1.7-80 MHz).". Elementary school level research will tell you that the High Frequency (HF) band actually only covers from 3.0 MHz to 30 MHz, so again your own "armchair media officers that still use kindergarten research material" have shown their level of incompetence.

Whilst I do not believe you are mature enough to admit your errors and apologise to the international amateur radio community for your misguided and inaccurate stereotyping, I can only hope that those in power will see your media release for the inaccurate, defamatory and poorly reasearched garbage that it is.

Yours most disrespectfully

Martin Howells

The statement about amateurs didn't strike me as stating what kind of
equipment would be effected, it seemed more an attempt to show amateur radio
operators as a group of ignorant, backwards idividuals.

Not only survived close encounters with the Hot Chassis, but I might have been killed several times over by fully active 5U4s. Yet I survived, thanks to BPL.

But how? Isn't BPL a new invention, far more recent than my clumsy repair efforts? Don't we have a temporal anomoly here? Consider that BPL will provide reliable broadband powerline access to everybody at a very low price. BPL will make power lines quieter. BPL saves lives. And I'm now sure the Rules of Time present no barrier to BPL.

I now realize that BPL exists outside the world of known physics. BPL has found a portal into the world of magical psudeoscience commonly found on Saturday morning cartoons and Star Trek episodes.

I have not looked at a CM in about 15 years but the one then that had 3 wires did not have any feedback to give any indication the antenna was even turning but relied on the two motors to turn at the same speed. The U-100 type rotators used a 4 th wire for the 'clicker'. The rotation on both types were determined by which one of the two winding got the direct power and which one was connected to the capacitor . It takes 3 wires to do that.

4518. inline swr meter question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-26 20:25:39 UTC
From: RB <rbig@bellsouth.nospam.net>
Message-ID: <qOkDc.2139$AN5.559@bignews2.bellsouth.net>
Source record: 92873

I have a very nice ham SWR meter that was bought in '74 timeframe in the electronics district in Tokyo. It is an inline Osker Block unit (never heard of 'em). I would like to use it, and think I can. But, need an understanding of how it works first, and this is what I'm seeking help on.

It appears it is designed for 75m-2m ops.

The unit is well built, and is a metal box approx 3" square on the ends, and 8" across the front. It has coax fittings on each end. There is a 75ohm/50ohm selector switch by one of the coax fittings. There are separate power and SWR panel meters in the box.

There is a calibration chart that is obviously used in conjunction with a small control device which is knob adjustable. It may be a var cap, or a variable resistor (pot). The calibration card has two control setting scenarios: one for 50 ohms, and one for 75 ohms.

The calibration card has different control settings for different power levels at the same freq.

I ASSUME the cal card setpoints are supposed to give me approx 0 meter reading if the xmtr signal is seeing close to 1:1 SWR. Is this likely correct?

And yes, I could easily rig things, using a coax switch, to where I could take comparative readings between the Osker and my normal SWR meter, and do a cut and try thing. However, it would be an inconvenience to have to do this. And, I figure there are people in this group who probably have the info I'm looking for at hand.

Hello,

First switch it to 50 ohms as that's what CB's use. While you hold the mic button in and transmit, put the meter to SET or CAL and adjust so the needle goes to the SET/CAL mark on the scale. Switch it to REF or reflected and it will show the SWR reading.
You need to adjust it if you change power by the way !

Am looking for some links to homebrew designs for a base station 2M colinear (two stacked 5/8 wave type). I prefer something simple made from PVC and wire. Any ideas considered.

Richard Feynman, after receiving a Nobel Prize in physics, was
honored at a ladies' club tea. The MC asked him to describe simply the
research for which he had been given the prize. He replied, "Madam, if
it could be described simply, they wouldn't have given me a prize."

4522. FM arial help

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-26 23:24:22 UTC

Message-ID: <cbl0j5$qd0$1@sparta.btinternet.com>
Source record: 92877

Hello,
Judging by your posts (I didn't understand one) this might seem obvious but I'm no radio expert.
I want to improve the FM reception in the house for my new DVD player (Sony DAV SC5 - excellent sound) and plan to run a co-ax cable to the attic. There is a spare tv arial up there from the previous owner. Will that be of any use or should I buy a dedicated FM arial, and if so what should I look for? I am in Scotland and the house is two storey so the attic is quite high up.

Thanks in advance.

Source record: 92878

Here's my note to the media assistant....probably won't do much good but I feel better anyway.

73 - Dino KLï¿½S/4

As a licensed amateur radio operator, FCC call sign KL0S, I am very concerned with the spectrum pollution (interference) associated with the new broadband over power line technology the FCC is considering for approval for use by the power line industry.

As a retired U.S. Army officer I have had extensive experience in radio communications operations under active electronic warfare conditions and many of the those experiences mirror the noise conditions that will potentially be generated by the BPL initiative.

The industry plans to use a form of power line carrier (PLC) technology using existing low and medium-voltage power lines to deliver broadband (internet) services to homes and businesses. It uses frequencies between 2 MHz and 80 MHz; and ARRL laboratory and in field tests have documented that BPL causes interference (spectrum pollution) to HF and low-VHF frequencies currently in use by the Government (Department of Defense and Homeland Security), law enforcement agencies, amateur radio and commercial businesses. Further, the current BPL technology itself may be susceptible to transmissions from other existing services.

To appreciate the level of interference, please visit the ARRL web page at [http://www.arrl.org/news/stories/2003/08/08/2/?nc=1] and listen to the BPL interference recorded from one of the FCC test sites. As I mentioned the noise portrayed eerily matches that encountered during electronic warfare conditions. Contrary to power industry claims, the ARRL tests convinced me the current BPL technology will generate major
interference to existing services, including amateur radio, public service and and potentially other Homeland Security communications activities such as those conducted under the MARS AND SHARES programs. The ARRL President, Mr. Jim Haynie is prepared to provide the FCC with more details. He can be reached at 214-366-9400 or w5jbp@arrl.org

Regarding the FCC Notice of Inquiry, I recommend tightening of the FCC Part 15 requirements and/or standards for power line carrier (PLC) devices to assure they will not cause interference (or be susceptible from) to existing services. In addition, I would appreciate documentation from the FCC that adequate testing has been performed to assure broadband over power line technology will not cause interference to existing services. Hopefully, this testing will be well documented and made public before the technology is approved for use by the power line industry.

I recently had occasion to work with my local power provider, Dominion Virginia Power on a power distribution system generated incidental radiator that caused significant noise at my home. The power company worked expeditiously to find and resolve the problem, however I can only imagine the magnitude of the problems that potentially will be initiated by BPL type incidental radiation levels. With only that small problem (a faulty underground cable splice) my ability to communicate was severely degraded, much to the same degree as discovered by the ARRL in their fact finding mission mentioned above.

All communicators, both professional and amateur sincerely hope the power line industry discovers a technical solution to the BPL interference issue so we can all enjoy the benefits of having broadband internet to our home via power lines.

Well, personally, I took offence at the general comments about amateur radio
operators:

"UPLC also commented on amateur radio opposition to the technology, urging
the Commission to ignore "armchair amateurs that still use vacuum tube
transmitters" and listen to the reputable companies and entrepreneurs who
are the real experts on BPL and who have overcome enormous technical
obstacles to make BPL a reality in the U.S. "

Of course, those in the USA will probably be disputing much more than just
that, but as I am not in the US I could not make comment on the entire BPL
issue.

No doubt, we in Australia will soon be facing similar debates as the BPL
experiments continue down here!!! It would be good if the FCC decides BPL
is too risky - kind of set an example that operators in other countries can
use to argue their point!

Cheers

Martin, VK2UMJ

You can try it, it won't hurt anything, but the TV antenna is for UHF unless it is very old, and since FM is a longer wavelength (VHF), it needs a larger antenna. On the other hand, just having some metal in the attic may work better than the present antenna. Give it a try, and if it is unsatisfactory, replace the TV antenna with a FM antenna.

The campus radio station (mid 1960's) at Ole Miss broadcast over
power lines. Quite unreliable but if one hasn't got a 'tenna,
then a cable will do and if you don't have a 'tenna, then God
bless you.

Not much on two meters, use 3/4 inch wooden dowl or acrylic rod for
supporting 3/4 inch tublar radiator. This also becomes the coil form for
thre matching coil. Groudplane can be anythinh from stiff wire held on by a
radiator clamp to a metal roof. Even with the radials going nearly straight
down from the antenna it seems to work pretty well. Ive cobbled these to
gether in an hour or so and have spent all evening making one look pretty.
They both worked well and gave long service. Constuction goes a lot faster
once you get some experience on where to tap the coil and know how many
turns, One day I am going to write this down when I make one.However I find
that figuring the right lengths for the 5/8 is not nearly as fussy as doing
a J from scratch
I dont mind J antennas a a horizontal dipole on HF where the stub length is
convinent to handle. This can be a problem when you get on down in freq. I
can use one on 20 meters at this freq the stub works well as my transmission
line. For me J's work from 6m trhough 20 meters. Wouldnt dream of actually
buying one though.

BPL comes into your house at the power company service box. Even if you
don not connect to it.

It creates S9++ signals from 2 to 80 MHz.

You can't hear anything on your new 10,000 dollar ICOM 7800 or any other
radio except 'Data Hash'.

Is that clear enough??

4531. Re: Power Industry BPL Reply Comments & Press Release

>don not connect to it.
>

FACT: The Cedar Rapids deployment has a WLAN link from the pole. The wires carry the 2-80 MHz. How does that go from 2-80 MHz --into-- the house?

>It creates S9++ signals from 2 to 80 MHz.

FACT: Sure, if you drive your 1972 Nova with 'HAM ON BOARD' sticker (for example) under the power line, this is a consistently true statement. Otherwise, there are some, few, circumstances in which an unacceptabel (pun and sic intended) level of 'hash' will arise in that passband to the annoyance of some hams. Based on assumption, the number of hams affected nation wide is in the hundreds. For comparison, the number of hams affected by tower erection restrictions is in the tens of thousands.

>You can't hear anything on your new 10,000 dollar ICOM 7800 or any other
>radio except 'Data Hash'.
>

FACT: Sure, if very nearby and unfiltered, this could be a problem. However, the FCC rules require filtering for RFI mitigation in such circumstances.

>Is that clear enough??
>

FACT: A vocal minority of hams want to 'kill BPL'. As opposed to working with the power companies to fix the problem.

FACT: The press has used this exchange, in many circumstances, to view us with the jaundiced eye of being anti-technology and very out of date. Why is it that they just don't see it as reason to 'kill BPL'?

God Bless,

Chip N1IR

Go to the jamesmillenco.com web site and scroll halfway down page 1 for a photo of the coils in the rack. A further Google search will reveal many other pages with photos. The 60 - 150 coil is two turns of #20 wire 3/8" dia., and spaced about 1/8" apart out at the end of the plastic tube (inside it).

Otherwise, there are some, few, circumstances in which an unacceptabel (pun
and sic intended) level of 'hash' >>

Hmmm...ok, this is for "rural internet access." "Looking out the window, what
do I see? A POWER POLE!!" Oh, 50ft away or so from the house. Hmmm...BPL at
50ft....??!!?? (Oh, and the car is a T5 Volvo...5 spd manual, of course...no
stickers...just speed & style)

<< Based on assumption, the number of hams affected nation wide is
in the hundreds. >>

Of thousands? Last time I checked, most houses had powerlines SOMEWHERE in the
general vicinity.

<< FACT: Sure, if very nearby and unfiltered, this could be a problem. However,
the FCC rules require filtering for RFI mitigation in such circumstances. >>

See above. Ever tried to get the bloody power companies to fix an arcing
insulator??

<< FACT: A vocal minority of hams want to 'kill BPL'. As opposed to working
with
the power companies to fix the problem. >>

Hmm...Germany and Japan are a "vocal minority?" Both tried it, and discarded
it due to interference. THAT "fixed it," but good.

WLAN (mebbe 5.6 ghz or so? W/a cable feed?) is a good idea, tho. PLC is not.
Duke Power (Duke Energy) is working on some trials.....I unwittingly drove thru
one neighborhood w/PLC and later realized that I had done so....interference
ranges from S5 to S9+ on my mobile. The houses are not much farther away from
the PL than my mobile. Empirical data says that interference would be present
there, also. I had shut off the mobile as I wished to save my ears. Thought
something had started arcing nearby. Heh...and just wait 'til the sunspot
cycle starts back upwards....

A

The outer jacket of coax has some pretty bad properties at these
frequencies. Normally this is not a problem as it is generally just used to
keep water out of the coax. With the sleeve type antenna you are building
you are expecting it to be an RF insulator, a job it was never designed to
do. Ive found these work much better by cutting off the shield where they
fold back and replacing it with a length of Teflon insulted wire. Other
types of insulation may work as well but I have not tried it.

Source record: 92893

Thanks, George I just made one. I wound a piece of 1/8 th diameter
aluminum wire around a 3/8 th bolt. The leads on the coil to the meter are
that same 1/8 th wire, about 2 inches long.
I'm impressed that the grid dipper now produces 137.50 MHz when the dial
reads 130.00. Hows that for good instructions from you??
I can tweek the frequency later, but now I see that this meter doesnt have
alot os "power out".

The grid dipper needle doesnt get above 0.1 so the poor sensitivity is
going to make this meter difficult to interpret. I got a schematic with
this (eBay) grid dipper so I expect I'll be able to do something to get the
meter to read a little farther up scale.

I appreciate your help.

Thanks
Jerry

Smoking? No sir, I'm in BPL nirvana. BPL nirvana is the best sort of nirvana, because wishing for something makes it so. The only thing I haven't been able to wish away is the occasional cacophony of Cranky Old Hams. They sound just like my alarm clock.

However, I fear it may already be morning in America.

Hi all. I have for sale a Hustler RM-75-S assembly as came with a Hustler 5BTV. Use it to replace a bad one on your 5BTV, or turn a 4BTV into a 5BTV. Unused, in original shipping tube, complete with the whip and the little wrench for adjusting the whip. Came with a 5BTV a long time ago but I never put the 75M resonator on it. Best offer by 5 July over $15 + shipping.

Cheers,
Tom

It is true that at least one (proprietary - they're all proprietary)
implementation of BPL forgoes the issues associated with coupling around the
transformer that steps the MV distribution down to 220 VAC for the feed to
the house by using 802.11b to link from a distribution point (essentially an
802.11b access point) to the computers in nearby houses.

However ...

> >It creates S9++ signals from 2 to 80 MHz.

Even the "flavor" that uses 802.11b to get from the pole to your house
radiates a LOT of interference in the HF/low VHF bands it uses from the
(nearby) distribution lines.

The "main.net" system operated by PP&L in Emmaus, PA measured -60 dBm
(that's S9+13 dB) of interference in a 3 kHz bandwidth, using an "Outbacker
Joey" short whip clamped to the roof rack of my Ford Explorer.

That rendered 20m SSB signals in the range of -80 to -100 dBm (which would
normally be quite usable) unintelligible.

> and sic intended) level of 'hash' will arise in that passband to the
annoyance
> of some hams. Based on assumption, the number of hams affected nation wide
is
> in the hundreds.

I'm not sure where you come up with the assertion that the number of hams
affected is "in the hundreds."

Are you referring to the number affected by the current, very limited "trial
area" deployments of BPL? If so, the numbers are probably relatively small.
HOWEVER, if BPL is deployed more or less ubiquitously, there will be few

hams far enough from a power line to not be SERIOUSLY affected.

> For comparison, the number of hams affected by tower erection restrictions
is in the tens of thousands.

True, and that's a valid crusade as well, but how does the existence of that
problem imply that we should ignore the problem of BPL?
(Remember, BPL will not affect just those who want to/can afford to erect
towers, but ALL hams that use HF/6m ... even with simple dipoles or
verticals.)
>
> >You can't hear anything on your new 10,000 dollar ICOM 7800 or any other
> >radio except 'Data Hash'.
> >

> FACT: Sure, if very nearby and unfiltered, this could be a problem.
However,
> the FCC rules require filtering for RFI mitigation in such circumstances.

Right now, the FCC rules don't require squat other than for the Part 15
device (in this case the BPL system) to shut down unless/until interference
can be eliminated. The radiated emission limits for BPL are WAY too high.
The "mitigation techniques" that the FCC and the BPL folks pay lip service
to are not in place, nor is it at all clear that they will be effective,
even if the power companies are responsive (and we've seen how responsive
most of them are [not]).

> >Is that clear enough??

Is that clear enough???

> FACT: A vocal minority of hams want to 'kill BPL'. As opposed to working
with
> the power companies to fix the problem.

I don't see it as a "vocal minority" ... all of the hams I know are
concerned that BPL will trash the HF bands and that the FCC and the power
companies will do little/nothing about it (the FCC hasn't acted on
complaints thusfar ... they've been buried in OET rather than being dealt
with in accordance with the existing rules.)

If someone could show me a technically sound way that BPL could use the HF
spectrum without trashing us, I'd have no problem with it. The problem is
that, as it is, it *does* trash us in any area where it's deployed and there
is no solution in sight.

There is one BPL technology - from a company called "Corridor" - that
appears to avoid the problem by not using the HF/low VHF bands ...

> FACT: The press has used this exchange, in many circumstances, to view us
with
> the jaundiced eye of being anti-technology and very out of date. Why is it
that

> they just don't see it as reason to 'kill BPL'?

"The press" feeds on controversy and frequently distorts things - at best in the interest of making the story more "sensational, at the worst because they have taken sides and have their own agenda to promote rather than objectively and dispassionately reporting the facts.

FULL FACT: These levels are well documented and allowable within 33M of
any power line or household appliance.

> affected nation wide is in the hundreds. For comparison, the number of
> hams affected by tower erection restrictions is in the tens of
> thousands.

FULL FACT: I am able to purchase a house where there are no tower
restrictions. With BPL, I have no choice except to disconnect from the
power grid on a house far from powerlines. Infact, you would need to be a
mile from powerlines.

>>
> FACT: Sure, if very nearby and unfiltered, this could be a problem.
> However, the FCC rules require filtering for RFI mitigation in such
> circumstances.

FULL FACT: So far, none of the hams reported anyone adding filtering and
the BPL industry has been unresponsive. Also, I listen to radios in the
bands from DC to daylight. I prefer to listen to foreign broadcast along
with amateur bands. How would they be able to keep ALL the bands clean?
Blocking foreign broadcast in any country is against the international
law. Our government must protect these bands from interference.

>>
> FACT: A vocal minority of hams want to 'kill BPL'. As opposed to working
> with the power companies to fix the problem.

FULL FACT: Once BPL has a foothold, there will be very little chance of having any issues resolved. All the other countries who tried BPL dumped it.

> FACT: The press has used this exchange, in many circumstances, to view
> us with the jaundiced eye of being anti-technology and very out of date.
> Why is it that they just don't see it as reason to 'kill BPL'?

FULL FACT: The media is for big business, owned by big business and promotes big business. That is why the press has lost most all it's respect from the people.

> God Bless,
>

Pat;

I just measured the length of the fly lead on my plus. It measures 27 inches from the tip of the plug to the end of the wire. I hope that helps.

>> FACT: The Cedar Rapids deployment has a WLAN link from the pole. The
>>wires carry the 2-80 MHz. How does that go from 2-80 MHz --into-- the house?

Myopic views and a redefined issue to suit self serving logic solves
nothing. To this point it should be obvious that solutions are not
being solicited - as the administration and lobbyists see it, there is
no problem.

>> FACT: Sure, if you drive your 1972 Nova with 'HAM ON BOARD' sticker

The standard industrial-political complex branding of targets of
interest.

>>Based on assumption, the number of hams affected nation wide is
>> in the hundreds.
>
>I'm not sure where you come up with the assertion that the number of hams
>affected is "in the hundreds."

Such challenges are typically deflected by those entitled to revenue
enhancements (more properly known as the Wall Street Welfare State).

>> FACT: The press has used this exchange, in many circumstances, to view us with
>> the jaundiced eye of being anti-technology and very out of date.
>"The press" feeds on controversy and frequently distorts things - at best in
>the interest of making the story more "sensational, at the worst because
>they have taken sides and have their own agenda to promote rather than
>objectively and dispassionately reporting the facts.

I'm not sure which is worse, this contrivance of the "press" as a foil
(more static than signal); or the disconnect with the FCC's puppet
activities in the broader scope of aggregating media into fewer and
fewer hands. If the quote above is a complaint outside of this former
thread's narrow special interest, it should be obvious that this "new"
problem has been cultivated by the administration's puppet master
activity. With the balkanization of grievances, no one is worrying
about the greater systemic poisoning.

The stale right wing gasp of the threat of liberal media is out dated
and has been a wheeze for nearly two decades. They have been using
this eviscerated rag doll as a punching bag for so long, that all of
the stuffing has been scattered to the winds and it is simply a
tattered scrap of cloth whipping in the wind. Perhaps the right

whiners are complaining of rug burn as their limp wrists get caught up in the shreds.

I've been following this silly notion of petitioning the FCC for redress in just one particular - BPL - when the problem is obvious on the face of it: complete indifference from the outset due to the larger scope issues. Why do they have to listen anyway? How would you know if they did? We have just one advantage over the Reds who allowed their comrades to offer protest - we save money by not sending them to the Gulags. The discount for ignoring these "comments" outweighs the construction costs alone. [However, now that we are embarked on no-bid contracts (that same Welfare State again), then that may soon re-vitalize industries that the right wing has mined from the communist economic model.]

The entire mandate of the Communication Act of 1932 has been set out on the curb for pick-up and if it doesn't impact a QSO, I doubt if there would be any ruffled feathers here.

Such provincialism is self castration. Looking out for your(our)self(selves) and the Devil take the rest is a myopic attitude guaranteed to eliminate future generations.

> >
> How does the antenna differentiate between "noise" and a valid
> signal?

Antennas are not intelligent agents able to differentiate between noise and a broadcast signal. If the noise signal is generated a long distance from the antenna it will be received right along with broadcast signals. The only advantage some antennas would have here is its reception pattern where the antenna could be orientated to be relatively insensitive in the direction of the noise signal. This generally is not helpful for short wave signals though because they are generally too spread out directionally instead of looking like a point source to take advantage of antenna nulls. Another problem for most people is the fact that they cannot get the antenna up high enough for it to exhibit its directional characteristics to a great degree.

A local noise is another matter greatly affecting many peoples reception of short wave signals since many electronic devices around the home and neighborï¿½s homes generate noise. Here the type of antenna, how it is connected to the receiver, and where it is located on the userï¿½s property makes a huge difference on what may be heard.

Fundamentally, you want the entire antenna system to reject common mode noise since to a local antenna this is the mode in which, the local noise will couple to the antenna. You will want to use an antenna that is balanced (Hertzian) instead of unbalanced (Marconi). You might also want to consider using an antenna type that responds more to the magnetic field component of the radio wave instead of the electric. These two suggestions encompass the fact that most of the local noise energy reaching and coupling to the antenna is a common mode electric field and since the far field broadcast signals you want to receive is composed of both electric and magnetic the later will be enhanced at

the expense of the former.

The connection from radio to antenna is best shielded so you would use coax. You could use a balance line but they are harder to acquire, use, and still will not work as well as coax shielding against local noise.

The antenna would be located as far from the majority of local noise sources as possible on the property. Distance reduces the coupling to local noise sources.

4554. 80 meter multi turn loop antenna

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-27 20:43:24 UTC
From: Jaap <jaap.verheul@ditweghalenhetnet.nl>
Message-ID: <cbnbiu$60q$1@reader10.wxs.nl>
Source record: 92908

HI,

I'm thinking about building a multi turn loop for 80 meters, using in for TX and RX purpose.
This would be a loop thats 1 meter big and 5 turns. Is there anyone who has tried this before?

Jaap PA3DTR

Hi Tom,

You are correct about the QST reference. The article is entitled "A DoppleScAnt" by Terrence Rogers, WA4BVY.

The article is very positive about the method.

Your generosity should be much appreciated by someone.

73, Roger, W7WKB

And, another thought: Often times on ebay, and at swap meets, you will see
ones by Measurments Corp-- Model 59. (think some also calles "Boontown"
meters , were made in Boontown, N.J.) These were made even with modern
day houseings (saw one at the last local meet), and relatively CHEAP! These
come in 2 varieties- a LOW freq head (freq range unknown), and a HF-VHF
version 2.2 MHz to 400 MHz in 7 ranges, and have a 4 inch meter (great
for these fadeing eyes) But- make sure that these have all their coils, and
tuneing
head! Tuneing is quite smooth and freq is acurate - modification article
for them
is in vintage Ham Radio issue. Agree with george- selenium is probably
shot, as well
as filter cap., and tube probably getting quite old (glow violet?- its
"gassy", and migh
salvage it by keeping power on it for couple weeks, but cheap to replace)!
Good luck, either way! Jim NN7K

SNIP: Well Chip, since the pole is only 20 feet from the ham shack ...
What can I expect if it deploys here in suburban Concord NH?

30 uV/meter [AKA ~ S9] at 7 meters from the pole is pretty significant when my station is 7 to 10 meters meters from the pole.

RE: Cedar Rapids ... see below.

>
>>It creates S9++ signals from 2 to 80 MHz.
>
>
> FACT: Sure, if you drive your 1972 Nova with 'HAM ON BOARD' sticker (for
> example) under the power line, this is a consistently true statement.

SNIP: Well Chip, since 30 uV/meter at 10 meters puts me [at 7 to 10 meters from the pole] in the fairly close field what will my noise levels be?

> Otherwise, there are some, few, circumstances in which an unacceptabel (pun
> and sic intended) level of 'hash' will arise in that passband to the annoyance
> of some hams. Based on assumption, the number of hams affected nation wide is
> in the hundreds.

SNIP: There is NO BASIS for that assumption!! BPL has not been tested in an densely Amateur Radio populated community. I live in a small town of slightly more than 4500 people and we have eight [8] hams in town. There is approximately one [1] amateur operator for every 420 citizens of the USA. [700,000 hams/300 million citizens]. Where is the BPL data to support that assumption?

For comparison, the number of hams affected by tower erection
> restrictions is in the tens of thousands.

SNIP: Red Herring ... non sequitor. But, they can still operate with
'stealth antennas' and a quiet environment.

>
>
>>You can't hear anything on your new 10,000 dollar ICOM 7800 or any other
>>radio except 'Data Hash'.
>>
>
>
> FACT: Sure, if very nearby and unfiltered, this could be a problem. However,
> the FCC rules require filtering for RFI mitigation in such circumstances.
>

SNIP: The ARRL has entered the case of W0SR because mitigation has not
worked after more than 2 months of effort in the case of Jim Spencer,
W0SR, in Cedar Rapids Iowa, reference your statement above. Jim is in a
BPL test area and has been off the air for two months while the supplier
has tried unsuccessfully to mitigate the noise.
Reference <http://www.arrl.org/news/stories/2004/06/15/2/>

Boeing, a highly reputable Aerospace and Civil Aviation Corporation has
made the following comment:

"Boeing told the FCC that Commission-proposed interference mitigation
techniques "are INADEQUATE [emphasis added] to protect safety of life
aeronautical HF communications services." The aircraft manufacturer
urged the FCC to "carefully investigate these issues" before adopting
rules to authorize BPL networks in spectrum used by aeronautical HF
radio services."
[Ref: <http://www.arrl.org/news/stories/2004/06/24/1/?nc=1>

>>Is that clear enough??
>>
>

SNIP: The original request was for a simple and clear statement of the
issue. I offer that I made a simple [elementary school level] level of
issue statement. Make the principle point so that it is understood [As a
former teacher you recognize that a little hyperbole is an acceptable
part of the teaching tool]. Once the principle is understood then
advancing the discussion to a higher more mature level of understanding
is possible.

>
> FACT: A vocal minority of hams want to 'kill BPL'. As opposed to working with
> the power companies to fix the problem.

SNIP: In the absence of data to the contrary, I refuse to believe that
there is a non vocal majority who are advocating BPL. [The antithesis to
your hypothesis].
>
> FACT: The press has used this exchange, in many circumstances, to view us with

> the jaundiced eye of being anti-technology and very out of date. Why is it that
> they just don't see it as reason to 'kill BPL'?

Once again, STILL ??, the press is/maybe wrong!!

I understand that on 22 June 2004 President Bush made the following comments in a speech to the Department of Commerce.

" ... We need to get broadband to more Americans and so, therefore, I want to talk about two other ways to get broadband to the consumer. We need to use our power lines better. They go everywhere. It seems to make sense, doesn't it, if what you're looking for is avenues into the home. Well, electricity goes into the home. And so one great opportunity is to spread broadband throughout America via our power lines.

And one of the problems we've got here is that the Commerce Department has had to develop technical standards that will make sure that our broadband can go across power lines without unnecessary interference. So it's a technological problem. It's a technological issue. It turns out that sometimes the competition of broadband and electricity just doesn't go too good across one line. And so -- if I could put it in simple vernacular. And so, therefore, the Commerce Department is helping to sort through these issues so that broadband access will be available through -- by our power companies..."
[Ref: <http://www.whitehouse.gov/news/releases/2004/06/20040624-7.html>

So, the executive branch has made up it's mind. I wonder if there is credible and competent technical dissent in the Department of Commerce?

Chip, I am still waiting for public disclosure on successful mitigation techniques. My suspicion is that when Hams complain at a later date the argument will be dismissed as 'you had you chance and didn't make your case'. Capital Investment wins...

Successful mitigation for the Amateur Radio market requires suppressing 8 portions of the HF spectrum for a total of 4.25 MHz [Ham and MARS] or 15% of the available spectrum. Other licensed services will also require some level of mitigation. Where is the data that supports a successful mitigation technology? How much suppression is required and under what conditions ... -40 dB, -50 dB, etc. What is the capital investment for suppression? Is the Rate of Return equitable for our investors? What are the HF susceptibilities to 1.5 KW PEP within those 8 HF segments? Are additional suppression techniques required for susceptibility? Will susceptibility issues be local or distributed? What about the capital investment and rate of return on this issue?

If BPL is proposed in my area I will be at all meetings raising the mitigation technical and business issues.

You want it as short as is practical, to minimize stray inductance.

If I recall correctly, the instructions were to plug the connector
into the NC jack, measure the wire-to-ground so that it would be taut
when connected to the grounding point, and then move the connector
from NC to GROUND. This results in a fly lead which has enough slack
to allow a spring mount to flex without ripping the connector out of
the plug, but not enough extra length to add sufficient stray
inductance to de-tune the antenna.

I use a 1.4m diam single turn loop for 160-15m which is quite successful on
80m.

The ARRL Ant book says that multiturn loops aren't that much better than
single turn loops if the coils are too close. It might be better to use the
tubing to make a larger (3-4m?) single turn loop. The same source says that
radials can improve mag loop performance. However I found that 3 radials 2x
loop diameter made no difference.

You'd also have to decouple the coax shield from the antenna to
prevent signals or noise from carried on the outside of the shield
common-mode fashion from being coupled back into your
remotely located antenna.

Pete

Yes!

> You will want to use an antenna that
> is balanced (Hertzian) instead of unbalanced (Marconi).

With an unbalanced antenna you must take more care to keep common mode out of the feed system. It is not terribly hard, however, to reduce common mode coupling to negligible levels, even with an unbalanced antenna (see http://www.anarc.org/naswa/badx/antennas/low-noise_antenna.html). One may want an unbalanced system for other reasons. A balanced dipole close to the ground generally has a poor vertical radiation pattern, while an inverted-L is much better.

> You might also
> want to consider using an antenna type that responds more to the

> the expense of the former.

This claim is widely made in the hobbyist literature, but I've never seen any measurements to back it up. I've tried to check it myself, and found the opposite: close to modern sources of EMI, the field tends to be predominantly magnetic. You have to be very close the source to see any effect at all: beyond ~0.1 wavelength induction balances the field pretty effectively.

Jim

There was a decent looking Measurements Grid Dipper on eBay a few weeks
ago and I thought I'd win it when I placed a $ 75.00 bid. But when I got
outbid, I assumed that there was a rich market for the Measuurement-Boonton
meters, so I lowered my sights and got this Millen (minus coils) for $16.00.
I think this Millen will be fun to make work and I'm actually happy with it
now that George has shown me how to make the coil for the one frequency I'm
interested in.
The Millen has a jack that allows the user to include a meter in series
with the Millen meter. I plugged a 250 Microamp (FS) ammeter and think the
meter is OK for my use now.
The more I learn about Grid Dip Meters, the more respect I have for them.

Thanks for all the help and advice.

Jerry

They don't but if you go by the advice you generally get on the antenna group, you run an unshielded lead in (part of the antenna) right into the shack (big noise source). When I made my prior comments about the lack of consideration given to receive antenna, I was referring to the antenna group. I didn't realize that the message was cross posted. It just amazes me that they will debate a transmitting antenna to minute detail but receiving antennas deserve no consideration other than a random piece of wire thrown into a tree. Despite their often one sidedness I have learned a great deal from them and mean no disrespect.

Hi OM,

As generalizations go, this one falls short with them all.

We here at rec.radio.amateur.antenna often recite the credo that
"reciprocity rules." This means that all considerations given to a
transmitting antenna are equally applied to receiving antennas.

However, I am sure you are responding to the disparity in coverage
between receiving and transmitting antennas - and this is for good
reason. Reception and Transmission are NOT reciprocal operations. A
receiver has far more latitude to accomplish its goal than does a
transmitter. Unless you have an abysmal receiver poorly connected to
an inadequate whip, the stock receiver with a simple length of wire is
often very close to doing a good job. If the receiver suffers from
any of a multitude of issues, there is generally a solution that
answers the problem specifically. About the only thing you can do for
the transmitter is to turn up the power, or lower the transmission
loss. It stands to reason that our focus is on optimizing the loss
side of the balance ledger.

Returning to the credo of "reciprocity rules," any gain to the
advantage of a transmitter is enjoyed by the receiver and the SWLer
stands the same advantage. But if that advantage is measured at 3dB,
this has the significance of 50W in 100W compared to the SWL S-Meter
change from S5 to S6 (BFD). Even though it is the same 3dB, there is
the illusion of perspective (my 50W compared to your 5ï¿½V). If the SW
station is buried in S9 noise, then this is not an antenna problem
(unless you can null the noise out through careful lobe positioning).
Filtering and/or DSP stand to answer the problem, but these are
obviously not remedies to transmission issues.

There is another thread discussing the goal of constructing a small
loop for 80M reception (and how well 5 turns might achieve some
benefit). The same issues of loss prevail for the comparison of

Radiation Resistance to Ohmic Resistance for a 1 Meter loop. The loop Rr is in the thousandths of an Ohm and about on par for a small wire's Ohmic loss. There's that 3dB again and what concerns the transmission efficiency is far easier to tolerate with the receiver and its surplus of gain. If the SWLer pays attention to this issue as it concerns the transmission problems, then that SWLer stands to gain in the efficiency returned. However, this is not to suggest that there is an actual need to obtain this efficiency; but if the SWLer mismanages the construction, the topic is discussed to the necessary depth to correct it.

A simple basis of comparison will illustrate. Many SW radios have a ferrite stick antenna that will work with at least some stations (VOA, WWV, BBC and a host of others). Try transmitting through that same ferrite stick and it will be like trying to shout through a straw. Our only alternative is to add an amp, but the big KW is only going to render smoke.

First off I did not realize this was cross posted so this is my last
post to this thread.

I'm not not regurgitating hobbyist claims but my experience in this
matter. Although 0.1 wavelength is more than enough to cover a urban
lot and your neighbor at short wave frequencies theory does not do
justice to a non homogenous environment we all live in. Most electronic
noise generators do not have efficient antennas attached to them where
the environment easily distorts the electric fields. I have repeatedly
experienced predominantly voltage common mode coupling of local noise
sources. Without exception mitigation methods against voltage common
mode noise were always successful and current mode antennas always
picked up less local noise.

My main problems with noise have been the next door neighbors dimmer and
the transformer that threw out hash galore and took the electric company
about 2 years to fix. When it rained, or was cold enough for dew to
form, it was like a really annoying buzzer from about 0 to 10 MHZ. I was
overjoyed the night it blew up. It was "on the list" due to my nagging
them, but lightning did the job...

CW,

That is 'why' I set-up the "Shortwave Listeners (SWL) AM/FM Antennas"
eGroup on YAHOO !
SWL-ANT=> http://groups.yahoo.com/group/Shortwave-SWL-Antenna/

Most HAM are concerned about getting the most power transfer
into the Antenna and the greatest Signal Output from the
Antenna. This may not result in the best receiving antenna.
A better SWL Receive ONLY Antenna is usually a result of
a Clean 'outside' Signal with a "Low Noise" factor.

Yes the topic is SWL Receive ONLY Antennas.

RC,

In the same location using the same Antenna:

100uV of background noise being re-radiated by a Transmitting
Antenna that is being powered at 50W or 100W is simply not an
issue for the Amateur/HAM.
- Background Noise is NOT an Issue when thinking of Transmitting
Antennas that are Radiating Power in the Tens and Hundreds of Watts.
- For the HAM Signal-to-Noise is NOT a Transmission Antenna Parameter.

100uV of background noise being received by a Receiving Antenna
that is seeking a 25uV Signal is unacceptable for a SWLer.
- Background Noise IS an Issue when thinking of Receiving Antennas
that are 'acquiring' Radiated Power in the Milliwatts or micro-watts.
- For the SWLer Signal-to-Noise IS a key Receiving Antenna Parameter.

For Sale: Two HAMSTICKS. One for 10 meters and one for 15 meters. Traded in my Pontiac Montana for a Ford Focus because of high gas prices. But I can't fit the rig in the Focus. So selling the antennas. Still plenty of action on 15 meters, especially this coming fall/winter. And E-skip daily on 10 meters which is perfect for mobiles. ONLY $14.95 for BOTH! (Plus $9.95 Priority Mail shipping and insurance.) First e-mail gets them! wa8mea@hotmail.com - 73 from Bill, WA8MEA - REALLY NEAT STUFF at - http://qth.com/dwm

4588. best antenna over a carport?

Hi,

In my continual search for a halfway decent DX antenna situation for 20, 30, or 40 meters, I noticed that I have a carport approximately 120 feet long and 7 feet high and 15 feet wide. My car is at the very end of the carport, right across from my apartment, and my apartment is located on the lower floor.

The carport has florescent lights underneath every few cars, but is stuck in the asphalt and is therefore not connected to any ground! I am wondering if there is anything I can do with this?

1) Load up as is and work against a cold water pipe right underneath my apartment. Long wire?

2) Lay one insulated wire on top of the carport, terminate the wire at the far end with a resistor connected to the entire carport as artificial ground, and load up the local end. Classic single wire Beverage? Maybe two wires steerable Beverage?

3) Because florescent lights cause RFI across the entire band, lay a loop of very thin coax on top of the carport, interrupt the shield at the near end in order to connect with my tuner, and connect the shield to the carport and the water pipe for ground. Very long magnetic loop antenna with vertical lobes?

How good would any of these ideas be, or do you have any other ways to exploit a carport?

Thanks,

The Eternal Squire

Hello iane,

The construction of this "argument" is called a strawman. Who is to
say it "is simply not an issue?" Further, who is to say it is?
Amateur radios, as last I noted, contain receivers too and suffer
every much any debility as a SWL set. Simply put, there is no
separation to argue.

>- Background Noise is NOT an Issue when thinking of Transmitting
>Antennas that are Radiating Power in the Tens and Hundreds of Watts.
>- For the HAM Signal-to-Noise is NOT a Transmission Antenna Parameter.

Then why would you presume this is a fault in discussion here in an
antenna group? True this is cross-posted, but again, we have every
concern with reception that a SWLer would also have. Again, there is
no separation of issues to argue.

>100uV of background noise being received by a Receiving Antenna
>that is seeking a 25uV Signal is unacceptable for a SWLer.

Again, Amateur radio is just as concerned and seeks every remedy where
ever it may be found. To continue:

>- Background Noise IS an Issue when thinking of Receiving Antennas
>that are 'acquiring' Radiated Power in the Milliwatts or micro-watts.
>- For the SWLer Signal-to-Noise IS a key Receiving Antenna Parameter.

Antennas have no capacity to reduce Signal to Noise ratios except by
virtue of narrowing lobes to eliminate noise by placing it in a null
(if that is in fact a viable option either in the sense of having a
null, or having a null to a noise source that is not on the same
meridian as the signal of interest).

To this point, you have not offered any particularly receive dominated
issue that is not already a heavily trafficked topic with transmission

antennas. In fact, the presumption there are unique reception antennas that are more suitable than their transmission cousins is simply the artifice of my aforementioned advantage of the RF Gain control. It has been long established (through the simple act of purchase power) that receivers have far more gain available than needed except for the worst of antenna designs (and that has to be an exceptionally vile design).

Such examples of small loops used for MF are proof positive how poor an antenna can be, and the RF gain knob resurrecting its pitiful efficiency. This does NOT demonstrate some illusion of superior receive antenna design; rather it is more smoke and mirrors as an argument. Inverting the argument, if you had a full sized antenna for that band, you would only need a galena crystal and cat whisker to power your hi-Z headset. For DX you would only need a $5 AF amplifier. The smaller antenna clearly needs more dollars expended to offset the debilities of the poorer efficiency. The specious argument is tailored for the technically effete who would rather push a credit card across the display counter than build their own cheap solution. Take heart that this not simply a cheap shot, there are as many Hams who don't know which end of the soldering iron to pick up either.

4591. helicity on vertical dipoles

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-29 07:29:12 UTC
From: eternalsquire@comcast.net
Message-ID: <904dab11.0406282329.3246270c@posting.google.com>

Hi,

I'm considering a vertical dipole array, one each in 3 corners of a triangle around the outside of my apartment wall. I'm on the lower floor, of course. Each vertical dipole will be disguised as a stereotypical wooden birdhouse that you find at the craft store, supported by wooden poles with wire cores.

The reason I am considering the vertical dipole is so that I do not have to bother with a radial system, I would rather hide the grounding system inside the pole support.

Only disadvantage of the scheme is that my roof is only 25 feet high, and that the bottom of a vertical dipole should be 10 feet off the ground. Under normal circumstances a 40 meter vertical dipole at one quarter wavelength on the side wold be impossible. 30 would be extremely difficult, 20 just might be doable.

What I would like to try to do is shorten the elements of each dipole using helical winding rather than straight length wire. That way I can have the active elements closer to the roof or even a little above.

Question: to what extent can I shorten the winding while still retaining good signal apeture? about 50 %? More? And what would I need to do (if anything) to compensate for this?

Thanks in advance,

The Eternal Squire

Hi Andrew,

Unless this a continuation of your concern for stealth, I would suggest a GAP vertical antenna. However, the remaining discussion will presume your former interest.

>The carport has florescent lights underneath every few cars, but is
>stuck in the asphalt and is therefore not connected to any ground! I
>am wondering if there is anything I can do with this?

Suffer comes to mind. There is a ground (code demands it), however, it is a safety ground that in this case will probably not offer much RF relief. However, this presumes the lights are noisy which is not always the case. Most of this noise is through conduction and sharing of power circuits. To determine how much is over-the-air, simply scout the area with a small SW receiver with a whip antenna. Choose a set of frequencies to monitor (the ones you want to work would be suitable) and build a map of noise vs. frequency vs. position along this carport. There is no more successful answer to your query than direct experience.

>1) Load up as is and work against a cold water pipe right underneath
>my apartment. Long wire?

This will probably do just as well as any more elaborate design (including my already mentioned GAP).

>2) Lay one insulated wire on top of the carport, terminate the wire
>at the far end with a resistor connected to the entire carport as
>artificial ground, and load up the local end. Classic single wire
>Beverage? Maybe two wires steerable Beverage?

A Beverage is typically a very low sensitivity and low efficiency antenna that has the advantage of directional selectivity (AKA receive antenna). It would have to be several wavelengths long to achieve its vaunted attributes.

>3) Because florescent lights cause RFI across the entire band, lay a
>loop of very thin coax on top of the carport, interrupt the shield at
>the near end in order to connect with my tuner, and connect the shield
>to the carport and the water pipe for ground. Very long magnetic
>loop antenna with vertical lobes?

Uhm, "magnetic" antennas will work quite well in picking up noise,
especially the way you have described it.

>How good would any of these ideas be, or do you have any other ways to
>exploit a carport?

You are in a far better position to simply try and report back here
how it went - anything else is conjecture of the first water and would
save you nothing in effort.

Another alternative is to find about 100 to 200 feet of coax. Add a
choke to the far end. Build a simple 1 Meter loop and attach it to
the choke. Connect the other end to your rig. Get a buddy and two
HTs so data can be accumulated. Walk the area and map out the
interference levels over several bands (a variation of the mapping
described above). A bigger loop, such as you anticipate, will only
suggest more noise introduced - if you can't live with a small loop's
worth, you certainly won't find any relief with a bigger one. As a
cautionary note, making it a small dipole won't bring any more relief
either. Noise, such as you anticipate, is noise - indistinguishable
from DX.

Bill has overstated the "generally accepted" number of radials. AM broadcast stations will have 120 radials but I've never met a ham with that many and many thousands of us have worked the world with a lot fewer. It depends greatly on the quality of ground you have and that's not easy to determine before you begin. But after 8 radials, improvements with each additional radial become much smaller.

My advice, Gary, is to start with a few radials for each band and try it out. Here's the irony: if that works well, you will probably see an improvement if you double the number of radials. If it doesn't work well at all, you might try a different approach because adding more radials will not be too effective.

Nature is full of these ironies. My favorite is that when bread and crackers are exposed to the same environment, the bread becomes hard and the crackers become soft! (Posted on someone's door at Stanford Research Institue back in the 60's.)

75m mobile antennas are shortened by as much as 88%. Of course,
they are not very efficient. But a 50% shortening should result
in an acceptable amount of loss. However, hi-Q loading coils are
more efficient than helical windings. Tell everyone that the
loading coils are varmint guards (snakes, squirrels) for your
"birdhouses". A top hat could be disguised as bird perches and
would raise the efficiency of your antenna elements.

On another note, peak performance from a vertical array requires
phasing/matching at the feedpoints. Roy, W7EL, has a computer
program that will calculate the lengths of the phasing sections
for you - available at www.eznec.com.

ON4UN has a section on "Triangular Arrays" beginning on page 11-48 of "Low-Band DXing". Check the rest of the book. Use vertical polarization if you have good soil conductivity or adequate radials. Otherwise, horizontal polarization may work better. Avoid inductive loading of short verticals. Instead use capacitive hats. The book is a winner.

Hi OM,

het van het kattenbakkebaard en loodglans kristal is de oude
componenten van de tijddetector. De bakkebaard van de kat is fijne
draad. Het kristal van het loodglans is semiconducting mineraal (waar
de draad raakt en contact met een oxyde opneemt). De twee componenten
maken een diode.

RC (KB7QHC),

Spoken (written) like a True Amateur, and precicly why most SWLs
ignore what is written in reply to SWL 'type' Antennas questions
by HAMs.

Most SWLs work to get the best signal (cleanest signal and lowest
noise) they can to be able to listen to what they what to hear.

The HAM would hardly ever consider a 'random' wire Antenna;
but to the SWL'er the "Random" Wire Antenna 'concept' is a
natural to fill their available space. Power handling, gain
and antenna design characteristics are the focus of the HAM.

As far as the AM/MW Loop Antenna's are concerned. For the AM/MW
DX'er these Antenna's perform the best for their size and the
available space that the average Broadcast Listener (BCL) has
for these Medium Wave Band. The SWL'er wants to hear any Radio
Station out there from any direction.

The 'focus' of the SWL'er is simpy different then the Amateur;
and the majority of SWL'ers are Program Listeners who seldom
listen to the HAM Bands.

Strange logic to offer that a listener comes here to post a query they will ignore in anticipation. Rather self serving argument isn't it?

>Most SWLs work to get the best signal (cleanest signal and lowest
>noise) they can to be able to listen to what they what to hear.

There is nothing in this statement that distinguishes amateur from listener. Further, it contains absolutely no technical material to support any sense of this exclusivity of concern. To respond in kind, you don't even rise to amateur status.

>The HAM would hardly ever consider a 'random' wire Antenna;

Now this is a statement that is clearly in error. The archives will attest to this.

>but to the SWL'er the "Random" Wire Antenna 'concept' is a
>natural to fill their available space. Power handling, gain
>and antenna design characteristics are the focus of the HAM.

As they are no more or less for a listener. If you find some other motivation, it is strictly your own prejudice.

>As far as the AM/MW Loop Antenna's are concerned. For the AM/MW
>DX'er these Antenna's perform the best for their size and the

Perhaps you should attend this board more often to learn the fundamentals. There is no impediment to hearing any Radio Station out there from any direction with simple verticals. SW sets come with them you know.

>The 'focus' of the SWL'er is simpy different then the Amateur;
>and the majority of SWL'ers are Program Listeners who seldom

hello Arie,

thanks for your contribution... your figures come very close to my empirical data when analysing dipoles (of exactly the same length in exactly the same place on the same day in bright sunshine all day) for 14 MHz using different kinds of materials, insulations, thicknesses, diameters etc....
obviously there is a flaw in Roys formula as well... some people erroneously think that he employs NEC/4 with EZNEC 4.0 when taking wire insulation into consideration...

regards

Richard,
Probably to a lot of people a radio or electronic hobbyist is an "amateur".
Impression I get is that some CBers think so also. From looking at old
literature, the search for the holy grail of a noise free antenna, seems to
back to around T=0. It would help, if the manufacturers of SWL receivers
would add noise blankers in sub $500 radios. I did not see any in the AES
catalog below that price that claimed to have a noise blanker. I won't even
delve on IF filter shape factor.

ps. I can beat your 40 years by about 10.

Not true. You are making the assumption that that the antenna only picks up radiated modes. Non-radiated electromagnetic modes are also troublesome, particularly common mode on the transmission line. This tends to be the way that locally generated noise from household gadgets gets into an antenna system.

Consider a lamp dimmer that generates 10 mW of RFI, which rides out in common mode on the mains, finds its way to the power cord of your transceiver, rides out on the feedline to the antenna, and then couples back through differential mode to your receiver input. That's not a very efficient coupling path, so suppose it has a loss of 60 dB. You'll still get 10 nW to the receiver. This is a lot: even if it's spread over 30 MHz, it's still 10 uV in a 6 kHz channel. That's S6 on my Drake R-8, a very serious quantity of noise.

On the other hand, if your transmitter puts out 1 kW, 60 dB of loss means it only delivers 1 mW of RF to the dimmer, an amount unlikely to interfere with its operation. Reciprocity does not mean *consequences* are symmetrical.

> To this point, you have not offered any particularly receive dominated

A deep, steerable null can be extremely useful for reception, but its not generally useful for transmission.

But for MWDX reception, efficiency simply isn't an important virtue.
Gain is cheap. What matters is the steerable nulls. An efficient
steerable MW antenna is enormous and expensive.

Sensitivity is the cheapest, easiest virtue to put into a receiver.
Essentially all modern receivers have plenty. Indeed, the cheap ones
often overload when presented with an efficient antenna: you have to
spend the dollars to be able to handle the big signals!

Speaking of strawmen, have you ever actually tried DXing with a crystal
radio?

I love designing and building antennas: applied physics is fun. But it's
good engineering to go with the strengths of your technology. For my
inverted-L's, I spend a little efficiency (4 dB or so) to get octaves of
effective bandwidth, something that is perhaps of little use to hams,
but is very useful to an SWL in conjunction with the frequency agility
of a modern receiver. 4 dB of efficiency loss is of negligible
consequence at HF and below if your receiver has a decent noise figure.
I've never seen mention of this efficiency/bandwidth tradeoff in the ham
literature, but it's not hard to find in the professional literature.
For details of a specific calculation, see:

I have a Fisher FM 2110 tuner Radio Shack antenna 20ft to 25ft high. What can I do to improver the recption that does not cost $$ I live in Houston Tx and want to get stations atleast 100 to 150 miles away.

Nothing that does not cost money, unless you have amplifiers and/or push-up poles in your junk box. Antenna mounted amplifiers will help, but you have to run power up to them, or use a photovoltaic array. Amps at receiver will not generally help. Probably the cheapest solution is to get the antenna at least another 10' up, more if possible.

Freshly baked bread is full of moisture, and a nice crisp cracker is dry.
After a while the bread loses its moisture and hardens, while the cracker
absorbs moisture and softens. Is this the moisture in the ground analogy you
are talking about?

Not so ironic at all. The bread lost it's moisture but the cracker
absorbed it due to the salt being a natural desiccant. The irony was
lost because the outcome was predictable.

OK, I know . . . no one likes a smart ass :-)

At 20 feet high your antenna can effectively see the horizon at about 6
miles from your house. So, to receive a FM station 150 miles away the FM
station needs to have it's antenna at an elevation of somewhere around 2
miles high. That is simply not feasible!!

At 100 miles the radio station needs an antenna about 1 mile high. Still
not feasible!

Basically, you should be able to receive a FM signal from a very well
equipped FM station out to 50 to 60 miles from their transmitting
antenna. Even at 60 miles the broadcast antenna needs to be around 2000
feet high.

Actually, it's Boonton, N.J., I've been to the
Measurements Corp factory. There was
another company there that used the name
"Boonton". I have one of their RF Voltmeters.

> ...These
> come in 2 varieties- a LOW freq head (freq range unknown), and a HF-VHF
> version 2.2 MHz to 400 MHz ...

One meter/power supply unit, three tuning
heads. Mine are packed at the moment,
but the LF head covers roughly 60 kHz to
2.3 MHz, the most common head covers
2.2 to 400 MHz, and the UHF head covers
up to about 1GHz, as I recall.

I have all three heads, and use them all.
Great instrument, but many newcomers
(even a Hewlett-Packard RF engineer I
once worked for) have never seen one.

>MHz, it's still 10 uV in a 6 kHz channel. That's S6 on my Drake R-8, a
>very serious quantity of noise.

Let's work with exactly that scenario you offered.

S6 (Calibrated) on my Drake TR-7 is -88dBm - so close to your 10ï¿½V to
be indistinguishable. My TS-430 varies from -80dBm to -73dBm. There
is no calibrated S-Meter for my DX-440, but for a $200 SW set, its
sensitivity is -90dBm for a full scale meter indication (about 7dB
range from top to bottom).

All very well and good. Now if we regard this speculation of 10mW (it
is, after all, the epitome of a wild ass guess, isn't it?); then,
let's reverse engineer that 10nW product from 6kHz buckets over the
range of 30MHz to find 50ï¿½W which is 23dB below the original power
presumably suppressed 60dB. Well, I have either pencil-whipped you,
or you me, or each other - the numbers don't add up. Hardly matters
given the original specification had no basis in fact.

However, if I return to the original "problem" of noise derived from
household sources; then that is also something I have closely
measured.

Across time, frequency, antennas, and known noise sources I have found
it as low as S1 for my longwire (an antenna supposedly unused by Hams)

to as high as S7 (for that same longwire). My loops, dipoles and verticals hardly fell outside of this range to present any gilt-edge design.

With every circuit in the house broken (operating battery power in the dark), average noise level was either S2 for a vertical, or S1 to S3 for a loop (rather upsetting the voodoo of loops being quiet and verticals being noisy). When I returned power to the house by stages, I insured every opportunity of injecting noise by setting dimmers to their worst position (about 50%). In the low bands, I suffered as much as S8 noise levels with an average of S5 when the house was full lit (also including fluorescents) and all noise sources adding to the cacophony of reception. This was for a loop antenna.

This effect of reciprocity has been reported so frequently in this group so as to negate your premise. We have many queries for how to solve this problem.

>not generally useful for transmission.

This really goes off the deep edge. Barring loss introduced for the sake of jimmying the logic, transmitters AND receivers enjoy the GAIN derived from the introduction of a null not otherwise part of the characteristic. This is a commonplace of theory and practice. Where ever you can design or contribute to a null; then this must of necessity result in an increase in signal outside of its region. These are all commonplace observations discussed here that are observable for either Ham or SWL operations. There is NO differential offered in these observations that separate SWL from Ham activities.

All of $20 if you have any technical capacity. Otherwise push the
credit card across the display counter and spend as much as they can
sell you. This argument is like driving your car into the shop to get
the air changed in your tires every 100 miles.

Again, front end overload is a very common complaint offered here by
SWLers who are then advised in how to simply AND cheaply combat this
problem.

>Speaking of strawmen, have you ever actually tried DXing with a crystal
>radio?

Sure, what is so remarkable about that? Beyond this simple design,
ever hear of a super-Regen receiver? You don't need to spend half a
kilo-buck to get the same sensitivity and filtering is dirt cheap.
How about Q-multipliers? All such topics barely spread the wallet as
much as the illusion of more buttons make a better rig.

As I pointed out to Yahoo, if you choose to cripple yourself, then
slide on over to the shoulder and enjoy kicking up dust and rocks as
you travel down the road. a 4dB loss for an inverted L (hardly a SW
invention) is far too simple to remedy to make its suffering a boast
of martyrdom. It is a strange argument to offer that you can't afford
a $20 solution for your $500 set and $2 worth of wire.

>I've never seen mention of this efficiency/bandwidth tradeoff in the ham
>literature,

You haven't looked. Either contrived, wholly fictional, or accurately
represented, it is part of the stock in trade for selling antennas.
In this group, I would wager its discussion consumes more bandwidth
than bragging about how many QSL cards have been pasted to the wall.

>but it's not hard to find in the professional literature.

It would do you well to note that this "professional" whom you rely upon, John Kraus, is one of the most notable Ham Radio Operators frequently acknowledged and referred to here.

Do you or others have any actual differentiable discussion, or is this simply an outlet for appoligia for why it isn't worth the strain to lift a soldering iron when you can bench press a credit card?

Yeh, and my first experience with one was at a Ham, and now long retired Tektronix employee. always wanted one-- bought mine for around 60 bux! The interesting thing was , found 2 of them (SANS OSCILLATOR HEAD) for 10 bux, and one of them NOT the WW II version, but in a SQUARE, modern houseing ! Probably should have got them on spot, but then there is always next year!! Not much call, unfortunatly for great test lab quality equipment (too many appliance ops!) but then the more they DONT recognize this stuff, the cheaper it is for me!! Good Memories- from around 35 years ago! Jim NN7K

4629. Re: DXer needs help imroving fm recption

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-30 02:58:16 UTC
From: Bob Bob <bcnntp@optusnet.com.au>
Message-ID: <9rm9r1-87s.ln1@p400bob.lse.com.au>
Source record: 92734

Err isnt FM broadcast between 88-108MHz? There is some "bend" to those
frequencies.

The simple answer to the problem is;
- more antenna height
- low cable loss (preamp?)
- low noise figure (good preamp)
- directive/gain antenna

Each of these requires $$ and it is a case of how *much* better it needs
to be. I'd initially suggest a low noise preamp as having best bang for
the buck. You can certainly buy them but it may be worthwhile looking a
a low noise design from a handful of components (say $5-10) I built one
up once from (I think) an MRF901. Worked well for TV and FM radio.

And maybe go to 30ft on the mast. Local obstructions might be a problem
too. ie make sure that your 20ft pole isnt right next to a 18ft house....

Antenna gain is a tricky one because most designs arent quite wide
enough to cover the entire band with good gain. LPDA's and helixes might
do the job though. Depends though on what you want to spend or make.

I should also point out that if you have any strong local FM stations
preamps may get overloaded and not perform well at all.This is the price
you pay for putting a wideband amp at the RX front end.

Hope this helps

10 uV into 50 ohms is 2 pW, not 10 nW (E^2/R). 2 pW = -117 dBW = -87 dBm. Multiplying by 30000/6 = 5000 buckets makes 10 nW or -50 dBm. Cancel the assumed 60 dB loss and I get +10 dBm, or 10 mW. The numbers add up fine.

Just because you couldn't doesn't mean others can't. Look at the rest of the articles on the BADX site. Taking steps to minimize common mode coupling has worked very well for me, and many people tell me it works for them too.

You might also find the articles at http://www.qsl.net/wa1ion/ interesting, especially the one entitled "Another Look at Noise Reducing Antennas". Mark's antenna designs are generally useless for transmitting, but they make superb MWDX receiving antennas.

> offered in these observations that separate SWL from Ham activities.

Certainly there is. A narrow null takes little power from the pattern:
you get little gain by putting that in a broad lobe. For example, an
elementary dipole has, theoretically, infinitely deep nulls yet it only
has about 2 dBi gain. Now consider a phased array: small phasing errors
have little effect on the gain, but they can have a large effect on the
null depth.

When transmitting, you're generally interested in putting the power in
the right place, but when receiving you're often more interested in
avoiding picking up power from the wrong place. These considerations are
only weakly related.

Sure. Used them. Selectivity is *lousy*. For SW, I've gotten better
results with a plain regen. Still, my Drake R-8 is better for DX, my
Sony ICF-SW100 travels easy, and my Stromberg-Carlson 58-T sounds
wonderful, so I haven't played with a regen in quite a while.

> How about Q-multipliers? All such topics barely spread the wallet as
> much as the illusion of more buttons make a better rig.

I have a Heathkit Q-multiplier I built in 1965. It's pretty good at
nulling out unwanted carriers, but in peak mode the shape factor of a
single resonance is pretty poor. At the moment I don't have a working
receiver it's really suited to, but I have a Halli S-40 one of my
in-laws gave me, and one of these days I'll find the time to repair it
(it's in really poor shape). The S-40 could probably use a Q-multiplier
once I've got it in working order.

How would you undo that 4 dB loss without loss of bandwidth? I'm hardly
boasting of martyrdom anyway: a broadband inverted L is a fine general
purpose receiving antenna.

He knew a great deal about the full range of antenna designs and
applications, not just ham radio. And he sure knew his physics.

>
> Do you or others have any actual differentiable discussion, or is this
> simply an outlet for appoligia for why it isn't worth the strain to
> lift a soldering iron when you can bench press a credit card?

When a soldering iron is the best tool to get the job done, I lift a
soldering iron. The Stromberg-Carlson was a "bare chassis" restoration:
most of the resistors were >50% off value, the paper capacitors were
leaking, the electrolytics were dry, and one of the RF coils was open
(disassembling and reassembling the coil turret was a real pain). Still,
it was worth the work to get that wonderful sound.

The NASA certified techs I work with professionally tell me I'm pretty
good with a soldering iron, considering I'm a physicist. From them,
that's high praise :-)

Thanks Jim, I have found some information on this sleeve dipole. I am
going to try one from 1/2" tube as outer and some 1/8" maybe up center
then a whip on the top. See if that will play or not. If not I may
make the Super J maritime antennas out of the antenna handbook. Yes I
know I could buy an antenna but that would be letting the dark side
win!! If I can't come up with something rigid and durable I will buy
one. Thank you everyone.

As I said, one of the two of us was being pencil-whipped. This does
nothing to change the fact that the original term has no basis in
fact. It could as easily be laid to the effects of a nuclear EMP 2000
miles away. There will always be something to blame, and that is NOT
a solution nor is it differentiable between Ham and SWL antennas.

>Just because you couldn't doesn't mean others can't.

Can't WHAT? The numbers I offer are shown of direct experience
correlatable to real world conditions and conform to 3 Sigma of SWL
conditions. Being correlatable they were also resolved and reduced to
that same unpowered baseline without forcing me off the grid into
darkness. My station sits with a noise flicker based upon
atmospherics and radiation borne products, not the usual household
pollution that I both describe above and eliminated through techniques
described as commonplaces in this group.

There are no magic antennas and no magic rituals equal to these
commonplace practices that are offered here.

>Look at the rest of
>the articles on the BADX site. Taking steps to minimize common mode
>coupling has worked very well for me, and many people tell me it works
>for them too.

This material is NOT novel by any stretch of the imagination.
However, it is hardly fully encompassing and falls short of the entire
treatment. The notion that a spike in the ground solves common mode
reveals a very limited experience in the matter, and simply devolves
to the misty eyed sentimentality of "it works for me, so there is no
better way for you." Testimonial is a poor substitute for how and why
- especially when the suggested solution inevitably fails for someone.
The common response in that situation is to sneer them away as somehow
deserving their predicament - again, with no one knowing the basis of
the problem, they can hardly help but repeat the same nostrum now
shown to fail somewhere (an anathema in religion).

>You might also find the articles at http://www.qsl.net/wa1ion/

These suggestions grow more bizarre by the posting where the
correspondent offers that SWLers ignore Amateur advice as poor quality
(a remark from a noted Yahoo), and then offer proof of their own
beguiling theories through quotes from - Amateur references.

>interesting, especially the one entitled "Another Look at Noise Reducing
>Antennas". Mark's antenna designs are generally useless for
>transmitting, but they make superb MWDX receiving antennas.

I cannot see how injecting the notion of uselessness is a boon for an
argument upon a physicist who can understand the notion of symmetry or
what is called in this field of study, reciprocity. If it is useless
as a transmit antenna, is it useless as a receive antenna? Of course
not, as such the injection of this comment serves no purpose other
than rhetorical noise.

The problem with such a degraded S/N in the correspondence of ideas is
that the larger body of uninitiated SWLers come to the conclusion that
this "uselessness" is a positive boon to be sought in every antenna
design. Our eminent Yahoo wears this badge of anti-intellectualism as
a patronizing populist.

This discussion also reveals a poverty of alternative designs that
have equal or superior merits, even if devoid of transmitting
application. Those designs are widely discussed here and their merits
are weighed not in prejudicial terms but rather in technical
comparisons and their correlation to application. That is to say,
anyone can make an informed decision on the basis of these evaluations
offered here where we typical discard "testimonials" to the rubbish
heap.

>A narrow null takes little power from the pattern:
>you get little gain by putting that in a broad lobe. For example, an
>elementary dipole has, theoretically, infinitely deep nulls yet it only
>has about 2 dBi gain. Now consider a phased array: small phasing errors

>have little effect on the gain, but they can have a large effect on the
>null depth.

Again, this exposes a lack of experience in the matter. Those nulls are balanced against the theoretical radiator called an isotropic source. This is the i of the 2dBi (and in fact is actual;y higher than that value).

Worse yet, this lack of experience further pollutes the uninitiated SWLer's notion of this balance of ledger because no one on this earth is ever going to experience that 2dB gain (nor the supposed sharp nulls) - and simply due to earth being nearby (an irreconcilable fact of life that extends out beyond 6 Sigma for the population of listeners). A simple dipole one quarterwave above earth exhibits an additional 3dB gain above and beyond your cited number. This goes to show how your casually abandoned 4dB for an inverted L is so simply recovered - through real comparisons rather than xeroxed theories.

The level of discussion is so unbalanced with myth, superstition and hearsay that the casual SWLer seeking advice faces the problem of sorting out the shit from the shinola. If I were to hike the dipole a little more, it shows 8dB gain after allowing a real world loss of 1dB. To tell that same casual SWLer 4dB is no great loss gives a spread of 10dB.

The consequence of this challenging this poor coverage of intellectual offering is that the casual SWLer having the facts known, can in fact choose to build a less optimal antenna, one that suits his real world limitations, and enjoy a design that does not simply discard signal with abandon. Alternatively, a simpler receiver can perform with an excellent antenna as well as a box full of expensive knobs can with an air cooled resistor.

>When transmitting, you're generally interested in putting the power in
>the right place, but when receiving you're often more interested in
>avoiding picking up power from the wrong place. These considerations are
>only weakly related.

This has been spoken too, the limitation is found in the signal and noise being aligned along the same meridian. If there is any weak relation it is found in the chance of distribution. The laws of reciprocity are not violated by chance, and both Ham operator and SWLer suffer the same odds. There is NOTHING separable here.

>> Who needs an efficient MW antenna?
>
>People who transmit, of course!

And SWLers are not transmitting are they? Really, these specious arguments do not advance any notion of this being separate issues. There is nothing in the circularity of logic that demands poorer transmit antenna designs are better receive antenna designs. Nearly every beneficial description from your sources cited above lie outside

of the antenna and reside in the coupling or in the receiver. Such commonplaces are not novel; they are not unique and special knowledge; and they are certainly not universally applicable.

>How would you undo that 4 dB loss without loss of bandwidth?

That has been responded to above. Loss of bandwidth is a chimera suited for argument rather than operation. To say it is frequency agile is the crowning claim for someone who is fain to turn a switch and set a capacitor in 5 seconds. This isn't rocket surgery, children learn such techniques within minutes of explanation and faithfully demonstrate far less loss consistently for ever after.

Further, the usage of a tuner solves many other ills related to noise and front end overload. The argument of the 9:1 transformer to ease operation comes at the expense of simple cheap solutions - to no great benefit, and further, to 4 dB additional loss as you describe. What boon is to be found in that combination?

I find it laughable that one web site offered claims that a resonant system is bad for your reception. What a crock! This has all the logic of buying square wheels to increase your gas mileage.

>I'm hardly
>boasting of martyrdom anyway: a broadband inverted L is a fine general
>purpose receiving antenna.

And what distinguishes it as a poor transmitting antenna? The inclusion of the engineering decoration of the 9:1 transformer? This logic is destroyed by a conventional tube transmitter (the original application suited to this design).

Once again, every issue in relation to even this point is discussed as a commonplace in this group with simple and cheap solutions that perform without the concurrent 4dB loss. Such a cavalier attitude of discarding signal is evidence of purchasing power, not technical competence.

>>>I've never seen mention of this efficiency/bandwidth tradeoff in the ham
>>>literature,
>>
>>

Wat een onzin Meindert, ik vraag gewoon of ze deze nieuwsgroep eruit
willen halen, het is en blijft een Nederlandse nieuwsgroep.

De 'draad' is gestart door Kees met reclame maken voor zijn website met
daarop zijn eigen gebouwde antenne, daar staat netjes bij dat hij wel
vragen wilt beantwoorden, nou prima maar dan wel op zijn e-mail adres
graag.

>want to get stations at least 100 to 150 miles away.

VHF basically is a line-of-sight service, although favorable propagation conditions can extend that range at some times of the day and seasons of the year, for some receiving locations. When those conditions exist, it doesn't take much of a receiving antenna. When they don't, no practical receiving antenna will work well.

For an FM station radiating 100kW from a 1,500 foot height above average terrain, at a 93 mile range the FCC's f 50,50 curves predict a field strength of about 75 microvolts/meter at a receiving antenna height of about 30 feet above ground. And that only occurs for "uncluttered" paths to 50% of locations at that distance, 50% of the time. Urban clutter and/or lower rx antenna height will reduce those fields strengths considerably.

As a cal point, my situation with St. Louis FM stations parallels the conditions above. Using a McIntosh MR-73 tuner with a Wineguard CH6065 10-element FM antenna (10dB gain), they are received with reasonable stereo quality about 1/2 the time.

Same reason prices are different at different places on almost
everything. WHATEVER THE MARKET WILL BEAR!

Why is plain salt $1.69 at Kroger and .98 at WalMart?

Why is soda at retail pricing normally 21 cents for 12 ounces at a
store or $2.24 per gallon retail if you look at it that way. But at a
restaurant (who buys it wholesale also, just as the store does) why do
they sell it for over $17.00 per gallon? Any price over 99 cents,
which represents 1000% markup is extortion on soda products!

4646. Outbacker Perth grounding question

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-30 15:51:05 UTC
From: "Bruce W.1" <bw@noDirectEmail.com>
Message-ID: <LjBEc.37229$cj3.17320@lakeread01>
Source record: 92751

I'm mounting an Outbacker Perth just above a long gutter and downspout. The gutter/downspout is the ground side of this antenna. This combination will be fed with 300 ohm twinlead.

The ground side of this has me confused. My question is this. Does the ground jack on the Outbacker need to be connected for it to work properly?

Why does the Outbacker even have a ground jack? A hamstick antenna doesn't have a ground jack.

If I was using a hamstick then one side of the 300 ohm twinlead would go to the antenna, the other side to the gutter/downspout. Simple.

If the Oubacker ground jack needs to be connected then should it go in series or parallel to the gutter/downspout? Or does it even matter?

In other words, should the feedline first go to the Outbacker ground jack, then on to the gutter? Or could I split the ground at some point near the antenna, run one wire to the Outbacker and the other to the gutter/downspout?

Thanks for your help.

The first dealer is based in Canada and the second is in the USA

$599 Canadian = $446 US which isn't too far away from the $380 price that CHQ are selling at considering (I believe) a generally higher cost of living in Canada.

My experience with the IC-2100H:

Had to replace a failing (25 year old) packet link radio.
Checked eBay, they were selling for $150 - $180 "New In Box".
Checked HRO, AES, etc. on the web.
Prices were $149 - $169 plus shipping.
Drove to Portland HRO, asked about price.
Store owner checked computer, looked at the big
pile of 2100Hs on the shelf, picked up a box, put it
on the counter and said "How about $135?".

Of course I bought some other stuff as well ;-)

Hi Thierry,

Manufacturer builds and sells (on average) to distributor (CHQ,
durhamradio, or Joe's Tap Dancing Academy) for $300. Manufacturer who
also advertises, offers MSRP (Manufacturer's "suggested" retail price)
or $599. This is only a "suggestion" but it establishes the "market
price."

Distributor #1 can sell for this price (customer pays the price
because that is what is advertised). Distributor #2 can sell for
more (customer tries to go to Manufacturer instead but is told to buy
through Distributor). Distributor #3 can sell for less (customer
abandons Distributors #1 and #2 like you). Everyone sells antennas
and is happy.

Soon Distributor #2 sells less than others and goes out of business
unless he has no bid contract to sell antennas for Halliburton.
Distributor #2 pays kick-back to Halliburton. Halliburton charges the
Taxpayer more money for "handling fees" and is twice as happy.
Congress over-appropriates funds for black project that Halliburton is
managing (for a fee) without oversight; and the price of the antenna
(on average) rises to $1200. $120 (10%) finds its way back into the
pockets of Republicans and they are happy. Instead of spending it to
generate local jobs, they put their money into off-shore investments
that are tax sheltered companies holding government contracts, and the
cycle starts all over again (happier yet).

Explanation: Capitalism (or the zero job growth economic boom).

Bruce W.1 <bw@noDirectEmail.com> wrote:

>The ground side of this has me confused. My question is this. Does the
>ground jack on the Outbacker need to be connected for it to work properly?

Yes.

>Why does the Outbacker even have a ground jack?

As I understand it, the Outbacker has a built-in matching network
which allows the (antenna radiation resistance + antenna loss
resistance + ground loss resistance) to be matched to a 50-ohm
feedline. As this total resistance often sums up to less than 50
ohms, an antenna of this sort is usually matched to the feedline using
an "L" network, which requires a connection to ground.

In the case of the Outbacker, I believe that the "L" consists of some
internal shunt inductance connected between the feedpoint and ground
(via the ground jack), and some series capacitive reactance created by
shortening the whip a bit.

If you leave the ground connection unattached, you're likely to find
that the antenna's feedpoint impedance is quite low when the whip is
adjusted for resonance.

> A hamstick antenna
>doesn't have a ground jack.

... and they are not always well-matched to a 50-ohm feedline.

A local Ham had trouble getting a low SWR with his Hamsticks,
especially after he improved the grounding between his feedline and
his vehicle chassis. I measured it out with an MFJ meter, and at
resonance the hamstick's feedpoint impedance was somewhere down in the
15-to-20-ohm range.

He purchased a set of air-wound coils, which connect to the antenna's
3-24 bolt and which have an alligator-clip-equipped lead which goes to
ground. With the correct clip positioning, and a slight readjustment
of the whip length, he now has a 1:1 match.

The Outbacker antennas do the same basic thing, but using an internal
(non-adjustable) matching component.

>If I was using a hamstick then one side of the 300 ohm twinlead would go
>to the antenna, the other side to the gutter/downspout. Simple.

You may or may not get an acceptable impedance match that way. No guarantee.

>If the Oubacker ground jack needs to be connected then should it go in
>series or parallel to the gutter/downspout? Or does it even matter?
>
>In other words, should the feedline first go to the Outbacker ground
>jack, then on to the gutter? Or could I split the ground at some point
>near the antenna, run one wire to the Outbacker and the other to the
>gutter/downspout?

What I'd do would be to minimize the length of the ground lead between the Outbacker and the feedline, and run as heavy as convenient a grounding wire or strap to the gutter. This would mimic a proper automobile installation.

I was wondering what effect aluminum foil (used as a radiation heat shield) would have on GPS signal reception? The scenario is a small payload container (approx 10" cube) covered in polystyrene, with a handheld GPS reciever located near the top on one corner.

Would aluminum foil on the inner sides (and/or bottom) interfere with the reception of the signal? I'm worried about possible reflection or other mechanisms of interference that might occur and prevent good reception. Basically, my question is, would foil on the sides or the bottom pose a reception problem? Are there any "configurations" that might not pose a problem? (i.e. 2 furthest sides only, half of bottom only, etc).

Thanks in advance for any insight!
Dave

I am adding in the sci.geo.satellite-nav newsgroup, as people there
are familiar with GPS antenna issues, and could explain this better
than I can.

First, you need to know what style of antenna your GPS has. Most are
either a patch antenna (the Garmin eTrex series) or a quad helix
antenna (some Garmin and most Magellan). The positioning and shielding
issues are rather different for the two.

You are right to be concerned about reflected signals, or multi-path,
issues. That can degrade accuracy.

Also consider a GPS model with provision for an external antenna,
which might give you more mounting options. You could have a
completely shielded box, with a passthrough for the GPS antenna cable,
to the antenna mounted completely outside the shielding.

Happy trails,

It is a reflector, and will change the pattern. How much depends on how the Al is configured to the antenna, and the spacing. The wavelength is about 1 foot, so your dimentions indicate that something will happen. (10 inch or 10 foot?) Quickest way is to just try it. The type of antenna the handheld has determines quite a bit too. THe antenna needs to see the sky, many times it dosent matter what it is mounted on, but then you have a handheld, that can be different.

==========

A multiturn loop on 80m is hopelessly inefficient for transmitting purposes. It is roughly 80 dB down on 1/4-wave vertical. Furthermore, for a Tx power output a lot less than a watt, the volts across the tuning capacitor will be 10Kvolts or more - if you can find or make one.

For the performance of multi-turn receiving loops download program RJELOOP3 from website below.

For the performance of single-turn transmitting loops download program MAGLOOP4.

Dit is niet de pot verwijt de ketel, enkel het laten zien aan de
engelstalige nieuwsgroeppen hoe hindelijk het is als er iemand in een
andere taal schrijft, als ze het dan proberen te vertalen in babbelfish
of een andere vertaalprogramma zullen ze zien dat er geen barst van
klopt.
Vandaar dat ik nu dus weer die engelstalige groepen die jij eruit hebt
gehaald erbij heb gezet :-P

Mike, I live on a rock here in central Texas. My service ground is 75
feet of #6 copper laid in the bottom of the electrical trench. I also
have a 6-foot horizontal ground rod laying on the rock with a few
inches of dirt over it and located where the feed lines pass through a
grounded metal bulkhead in the house wall.

The tower ground is via a couple of horizontal ground rods driven
between a couple of layers of rock near the base of the ower. The
tower is pretty much the highest object within a 0.75 mile radius, and
I've had one hit in the past 15 years. The only serious damage was
the stinger on the 2M Isopole at the top of the tower, and the
processor in the PK-232.

My neighbor had lightning rods installed on her metal-roofed house,
and they brought all of the ground cables down to several 2-foot
square copper plates laid right on the rock and covered with a few
inches of dirt. (Capacitive coupling?)

For RF ground, your best bet is radials and counterpoises.

Good luck,
Ed Bailen - N5KZW

The Outbacker or the Hamstick are not usually fed with 300 ohm line. I have never used either, but it is my understanding they are both designed for mobile operation and a 50 ohm feed.
If you are planning to transmit with the Outbacker fed with 300 ohm line you will need a Balanced Antenna Tuner at the shack. Even with this arrangement, I would not expect very good results because of ground losses and a low radiation resistance at the antenna input. You will be feeding a very unbalanced antenna with a balanced transmission line. My suggestion would be to feed the antenna with 50 ohm coax, and adjust the antenna for the best match at the transmitter. And yes, you will still need to connect the antenna ground jack to some sort of ground.

I'd expect this to be alright as long as the GPS antenna still has a clear view of most of the sky - i.e. if you imagine your eye being at the location of the antenna, it should be able to directly see most of the sky without needing to look through any aluminum foil. Multipath problems from reflections tend to be more of an issue when the direct path is blocked so the receiver only gets the reflected signal and when the path length of the reflected signal is substantially different than it would be for the direct signal. Neither would be the case here. There could still be some destructive interference from reflected signals but that problem is minimized if the direct signal path is unobstructed and therefore the strongest signal and by the selective antenna gain for signals of the proper circular polarization.

4665. Re: NEC/4 with EZNEC 4.0

Newsgroup: rec.radio.amateur.antenna
Date: 2004-06-30 23:06:28 UTC
From: Roy Lewallen <w7el@eznec.com>

Source record: 92770

EZNEC, EZNEC+, and EZNEC-M, of all versions including version 4.0, do not use any part of NEC-4 for any calculations. The geometry check and the wire insulation features perform the same functions as similar NEC-4 features, but they are implemented with independently written code that is not part of, copied from, or derived from NEC-4. I have been very careful about this, because NEC-4 is copyrighted software.

EZNEC/4 of all versions including v. 4.0 does use NEC-4 for calculations including wire insulation. Because the EZNEC geometry check feature detects more problems than the corresponding NEC-4 routine (SEGCHK), the EZNEC feature is used for that function by default. However, the user can choose to use the NEC-4 function, or both, if desired. EZNEC/4 is sold only to people or companies who have already purchased an NEC-4 license from the copyright holder.

In the tests I've run (by no means a comprehensive group of tests), the EZNEC insulated wire routine gives answers very similar to those given by NEC-4. I'd be very interested in any case where they significantly differ.
